THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

VOLUME XI.

FROM MAY 19 TO NOVEMBER 10, 1883.

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.

LONDON:
Printed and Published by JAMES GRAY, at the Office, 396, Strand, in the City and Liberty of Westminster.

1883.

INDEX TO VOL. XI.

57281

A

Abdank-Abakanowicz, M., New Magneto Call Bell, 368, 569.
Accumulators (*see* BATTERIES, Secondary).
Alternating Currents, Energy lost by Radiation from, by Professor Fitzgerald, 518.
American Telegraphists, Strike of (Leading Article), 252.
Andersen's Cut-out, 518.
Animal Electricity, Galvani and, by Professor M'Kendrick, 472.
Annunciator for Telephonic Purposes, designed by M. Volk, 203.
Arc, Electric, Discovery of, 162.
Arc, Electric, Resistance of, by O. Frölich, 150.
Arc Lamps :—
Brush at Vienna, 421.
Results of Tests at Munich, 566.
Artificial Lighting, 259.
Ayrton and Perry, Professors, Their Tests of Motors, 24, 307, 326, 355, 376, 402.

B

Bagot, A. C., Application of Electricity to the Working of Coal Mines, 272.
Balance, A Delicate, Suggestions for Using, by Lord Rayleigh, 474.
Banding, Machine, by T. H. S. Hawker, 559, 593.
Barker, E. R., Mance's Battery Test, 199.
Batteries, Primary :—
Chemical Corrosion of Cathodes, by G. Gore, 213, 233.
Chloride of Silver, Electric Discharge with, 133.
The Combination of Cells, by J. T. Sprague, 587.
Combined Insulite Battery and Annunciator, 164.
Mance's Test, by E. R. Barker, 199.
Batteries, Secondary :—
by C. H. W. Biggs and W. W. Beaumont, 494, 517.
and Dynamo, New Method of Coupling, by G. Kapp, 127.
The Elwell-Parker, 130.
Hallwach's Experiments, 81.
by C. T. Kingzett, 37.
Lane-Fox Distribution System at Vienna, 422.
Sellon-Volckmar at Vienna, 424.
Use of, for Industrial Purposes, 609.
Beardslee Fuse Exploder, The, 536.
Bell, New Magneto Call Bell, 368.
Belting, Machine, by T. H. S. Hawker, 559, 593.
Bernstein's Lamp at Vienna, 447, 610.
Betting and Telegraphy (Leading Article), 516.
Biggs, C. H. W., and Beaumont, W. W., Secondary Batteries and the Economical Generation of Steam, 494, 517.
Blakesley, T. H., Electricity at the Board of Trade, 425.
Board of Trade, Electricity at, 425.
Boat, Electrical (*see* LAUNCH).
Bolometry, Experiments in, by Prof. S. P. Thompson, 491.
Books Received, 168, 288.
Books, Reviews of (*see* REVIEWS).
Boys' Engine Power Meter, 186.
Boys, C. V., Meters for Power and Electricity, 110.
Bracket for Wires, Johnson and Phillips, 393.
Breguet's Torpedo Firing Machine, 426.
Brighton, Electric Railway at, 368.
Brighton, the Lighting of the Pavilion, 175.
British Association, Southport Meeting, Papers Read, &c.—
President's Address, 450.
Report of Committee on Electrical Standards, 465.
Leading Article on, 468.
Telegraphic Inter-communication, by W. H. Preece, 470.
Galvani and Animal Electricity, by Prof. McKendrick, 472.
Suggestions for Facilitating the Use of a Delicate Balance, by Lord Rayleigh, 474.
Fire Risks of Electric Lighting, by K. Hedges, 474.
Dr. Gladstone's Address to Chemical Section, 478.
Electric Tramways, by M. H. Smith, 487.
Experiments in Bolometry, by Prof. S. P. Thompson, 491.
Secondary Batteries and the Economical Generation of Steam, by C. H. W. Biggs and W. W. Beaumont, 494, 517.
Energy Lost by Radiation from Alternating Currents, by Prof. Fitzgerald, 518.
Producing Electro-Magnetic Disturbances of Short Wave, by Prof. Fitzgerald, 519.
Imperfection of Galvanometer for Testing Evanescence of Transient Current, by Lord Rayleigh, 520.
Magnetic Susceptibility, &c., of Soft Iron, by Prof. J. A. Ewing, 545, 571.
Prof. Henrici's Address to Mathematical and Physical Section, 550.
Brush Lamps and Machines at Vienna, 421, 469.
Budde, M., Death of, 373.
Burton, C. J., and A. P. Laurie, Heats of Combination of Metals with the Halogens, 202.

C

Cable, Manufacture, Improvements in (Leading Article), 324.
Cable Repairing, Some Notes on the History of, 606.
Cables, the Spanish National, 430, 454.
Cable Work, Forster's Translation for, 512.
Call Bell, Magneto, New, 368, 569.
Cantor Lectures (*see* REYNOLDS).
Carhash, Professor N. S., The Magnetophone, 418.
Cathodes, Chemical Corrosion of, by G. Gore, 213, 233.
Cayley, Professor A., Address as President of British Association, 450.
Cells, Their Combination into Batteries, by J. T. Sprague, 587.
Cheap Installations, 132.
Chloride of Silver Battery, Electric Discharge with, 133.
City and Guilds of London Institute, 420.
City and Guilds Institute, Examination Papers, 106.
Claverie, Ch., Horizontal Capillary Electrometer, 449.
Coal Mines, Application of Electricity to the Working of, 272.
Collieries, Electric Light for (Leading Article), 108.

COMPANIES' MEETINGS, REPORTS, &c. :—
Anglo-American Telegraph, 264, 310.
Birmingham and Warwickshire Brush, 260.
Brazilian Submarine Telegraph, 552, 598.
Brush Electric Light of Scotland, 191, 480, 502, 552.

COMPANIES' MEETINGS, &c. (*continued*) :—
Consolidated Telephone, 46, 71.
Cuba Submarine Telegraph, 312, 335.
Direct Spanish Telegraph, 286, 456, 499.
Direct United States, 240, 263.
Eastern Telegraph, 192, 215, 238.
Edison Electric Light, 502,
Electric Sun Lamp and Power, 46.
Faure Electric Accumulator, 71, 167, 616.
Globe Telegraph and Trust, 286.
Great Western Electric Light, 384, 407.
Hammond Electric Light, 615.
India Rubber, Gutta Percha, &c., 262.
Jablochkoff Electric Light, 525.
Lancashire and Cheshire Telephonic Exchange, 360.
London and Globe Telephone, 191.
London-Platino Brazilian Telegraph, 24, 71.
London and Provincial Electric Light, 383.
Maxim-Weston Electric, 47.
Mediterranean Extension Telegraph, 406, 500.
National Telephone, 288, 311.
Oriental Telephone, 67.
Pilsen, Joel, and General Electric Light, 336, 358.
Spanish National Telegraph, 431.
Submarine Cables Trust, 70.
Submarine Telegraph, 287.
Swan United Electric Light, 501.
Telegraph Construction and Maintenance, 262.
Telephone Company of Ireland, 431.
United Telephone, 261.
West Coast of America Telegraph, 216, 240.
West India and Panama Telegraph, 24, 45, 599.
Yorkshire Brush Electric Light, 527, 576.

COMPANIES, NEW (*see* NOTES).

Compass, Deviation of, in H.M.'s Ships, 130.
Conductors, the Size of, for the Distribution of Energy, by T. Gray, 439.
(*see also* STREET MAINS).
Congress on Electric Units, Report of Committee of Advice on, 429, 455.
Conversazione at National Telephone Co.'s Offices, Glasgow, 576.

CORRESPONDENCE :—
Aberdeen, Brush System at, 15.
Accumulators (*see* BATTERIES, Secondary).
Adams, M. F., Fisheries Exhibition, 231.
Almond, G., Earthquakes and their Origin, 57.
Animal Magnetism, 513, 591.
Arc Light Register, 177.
Archbishops, 253.
Ayrton and Perry's Motors, 58, 491, 515.
Bandsept, A., Delafield's Unipolar Dynamo, 466.
Bandsept, A., The Griscom Motor, 400.
Bandsept, A., Transmission of Power, 13, 107, 374.
Banding, Machine, *Errata*, 593.
Barker, E. R., Mance's Battery Test, 323.
Batteries Primary :—
Emmens', 283, 302.
Leclanché, 85.
Mance's Test, 230, 323.
Batteries, Secondary :—
A Cure for Spluttering, 205.
Faure-Sellon-Volckmar at Vienna, 15.
" Professor Forbes'," 253.
Retention of Charge by, 400.
Beckingsale, E. W., Brush System at Aberdeen, 15.
Bennett, A. W., Medical Electricity, 109, 205, 254.
Berliner, E., Microphonic Contacts, 33.

Digitized by Google

CORRESPONDENCE (*continued*):
Bottomley, W. F., Seismic Disturbances, 443.
Brown, J., Fixing Magnetic Lines of Force, 205.
Brush System in Aberdeen, 15.
Cable, Multiple, Singling out a Strand of, 355, 375.
Cables, Artificial Submarine, 442.
Carbon Blocks, 355.
Carpenter, W. L., Medical Electricity, 179.
Carr, J. J., Carbon Blocks, 355.
Clock, Electric, An Early, 467.
Crompton, R. E., Lighting of Nottingham, 14, 34.
Crossley, F. W., Gas Engines and the Future, 57.
Current Energy, Note on, 230.
Deprez, M., His Experiments, 13, 107, 374.
Dixon, W. H., Our Telephone System, 565.
Dowson, H., Leclanché Cells, 85.
Dynamos:—
Defective, 607.
Defective Field Magnets in, 566, 593.
Delafield's Unipolar, 466, 514.
Double-wound, 34.
Endless Chain, 593, 607.
Earthquakes, 443.
Earthquakes and their Origin, 57.
Educational, 302, 323, 375.
Electric Launch at Vienna, 491.
Electric Light Inquiry in Edinburgh, 89.
Electric Light Register (Arc), 177.
Electric Lighting at Aberdeen, 15.
Electric Lighting for Nothing, 32, 58.
Electric Lighting of Nottingham, 14, 34.
Electric Lighting at Vienna, 15.
Electric Railway (*see* RAILWAYS).
Electrical Machines and the Transmission of Power, 13, 107, 374.
Electricity: What is it? 301.
Electro-magnets, Winding of, 159.
Emmens' Battery, 283. 302.
Ermacora, Dr. G. B., Endless Chain Dynamo, 593.
Exhibition, International Electrical, at Vienna, 442.
Fault Localisation by Fall of Potential, 85.
Field Magnets, Defective, 566, 593.
Fisheries Exhibition, 230.
Fogerty, J., Vienna City Railways, 541.
Forbes, Professor, His Accumulator, 253,
Force, Fixing Magnetic Lines of, 179, 205.
Frankland, E., Retention of Charge by Storage Batteries, 400.
Gas Engines and the Future, 57.
Glass, The Passage of Electricity through, 110.
Gramme Ring, 16, 33, 88, 109, 128, 160, 179, 230.
Gravitation, Law of, 254.
Griscom Motor, The, 400.
Gülcher Lights at the Fisheries, 254,
Harrison, T. H., "Sheepish," 254.
Hawker, T. H. S., Machine Banding, 593.
Heaviside, Oliver, Ohm's Law. Prof. Minchin's Corollary, Archbishops, 253.
Higgs, Paget, The Gramme Ring, 33, 109,
Higgs, Paget, Double-wound Dynamos, 34.
Incandescent Lamps, Brush's Shield for, 58.
Information Wanted:—
How to Make a Magneticon, 33, 57, 205.
Medical Electricity, 109, 159.
re Ayrton and Perry's Motors, 491, 515.
Jackson, J. E., Electric Light for Nothing, 58.
Johnstone, J., The Passage of Electricity through Glass, 110.
Kauke, W. E., The Action of the Telephone, 230.
Kennelly, A. E., Fault Localisation by Fall of Potential, 85.
Kent, H. A., Medical Electricity, 229.
Kent, H. A., Photo-electric Generators, 593.
Launch, Electric, at Vienna, 491.
Lightning, The Reference to it in the Psalms, 129.
Lightning Conductors, Testing, 34, 58, 90, 109, 128, 159, 177.
Lines of Force, Fixing, 179, 205.
Lodge, O. J., Ayrton and Perry's Motors, 58.
Machine Banding—*Errata*, 593.
Magnetic Lines of Force, Fixing, 179, 205
Magneticon, How to Make a, 33, 57.
Magnetism, Animal, 513, 591.
Magnetism, Medical, 57, 109, 179, 205.
Magnets, Electro, the Winding of, 159,
Magnets, Field, Defective, 566. 593.
Mance's Method, 230, 323.
Manne, J., Rysselberghe Experiments, 467.
Medical Electricity, 109, 179, 205, 229, 254, 355.
Microphonic Contacts, 33.
Minchin, G. M., Note on Current Energy, 230, 253.
Mordey, Wm., Fixing Magnetic Lines of Force, 179.
Mordey, Wm., Gramme Ring, 88, 128, 179.

CORRESPONDENCE (*continued*):
Motors, Ayrton and Perry's, 491, 515.
Munro, J., Telephones, 34.
Natural Forces, Utilisation of, 593
Nell, P., Medical Electricity, 355.
Nottingham, the Lighting of, 14, 34.
Offor, G., Brush's Shield for Incandescent Lamps, 58.
Ohm's Law, 253.

Strong, J. B., How to Make Dead Telephones Talk, 89.
Submarine Lines, Artificial, 442.
Syphon Recorder, The, 179, 254.
Telegraphs, History of, 129.
Telephone, The Action of, 230.
Telephone, Experiments in Belgium, 467.
Telephone, The Invention of, 467.
Telephone System, Our, 565.
Telephones, Dead, How to Make them Talk, 89.
Telephones, Theiler's, 15, 34.
Theiler, R. and M., Telephones, 15.
Thermopile, Clamond's, 58, 89.
Toothache, Stopping the, 355, 607.
Tourtel, John, Electric Railway, 158.
Units, Electric and Mechanical, 301.
Varley, S. A., Artificial Submarine Lines, 442.
Varley, T., Electricity: What Is It? 301.
Vienna, Intern. Electrical Exhibition at, 442.
Vienna City Railways and Electricity, 541.
Vienna, The Sellon-Volckmar Battery at, 15.
Voice, E. L., Endless Chain Dynamo, 607.
Voice, E. L., New Unipolar Dynamo, 514.
Volk, M., Utilisation of Natural Forces, 593.
Werdermann, R. S. K., 467.
Whitehouse, W. H., Defective Field Magnets, 593.
Wilkinson, H. D., Mance's Method, 230.
Wright, Arthur, Arc Light Register, 177.

Correspondents, Answers to, 36, 60, 84, 108, 228, 300, 348, 372, 396, 420, 564, 588.
Creak, E. W., Deviation of Compass in H.M. Ships, 130.
Crompton, R.E., and Kapp, G., Current and Potential Indicators, 511.
Crossley's Exhibits at Vienna, 399.
Current, Potential and Resistance, by J. T. Sprague, 222, 280, 318, 416, 438.
Current Energy, by Oliver Heaviside 104, 149, 198, 246, 294, 342, 414, 510, 558.
Current Indicator, the Crompton-Kapp, 511.
Currents, Alternating, Energy lost by Radiation from. By Prof. Fitzgerald, 518.
Currents, Transient, Imperfection of Galvanometer for Testing Evanescence of, by Lord Rayleigh, 520.
Cut Out, Anderson's, 518.
Cut Outs, Hedge's, 82.

D

Davey Paxman and Co.'s Engines at the Fisheries Exhibition, 164, 201, 299.
Davy, Edward, Memoir of, 254.
Davy, Edward, and the Electric Telegraph, 181, 206, 224.
Deaths:—
Budde, —, 373.
Floyd, —, 275.
Niaudet, Alfred, 541.
Sabine, Sir Edward, 157.
Spottiswoode, William, 157.
Varley, C. F., 397.
Werdermann, R.S.K., 445.
De Meritens' Motor, Ayrton and Perry's Tests of, 378.
Deprez, Marcel, His Experiments on the Transmission of Power, 38, 475, 547.
Dvorak's Experiments on Electricity and Sound, 423.
Dynamo and Magneto Electric Machines:—
And Accumulators, New Method of Coupling, by G. Kapp, 127.
Beardslee's Fuse Exploder, 537.
Breguet's Torpedo Machine, 426.
Brush, at Vienna, 421, 469.
Edison-Hopkinson, 296, 546.
Ferranti, 631.
Gramme Fuse Exploder, 560.
Kravogl-Pfaundler, at Vienna, 490.
Results of Tests at the Munich Exhibition, 496.
Schuckert's, at Vienna, 519.
Schuckert-Brush, at Vienna, 470.
Siemens and Halske's Experiments with Dynamos of Constant Terminal E.M.F., 19.
Theory of, 366, 390, 462.
Theory of, by J. Joubert, 344.
Weston, at Vienna, 544.
Wheatstone's Fuse Exploder, 536.

E

Earth Currents, Apparatus for Automatically Registering the Strength of, 371.
Earth Currents, List of Works on, 455.
Earth Currents During the Sunda Straits Disaster, 595.
Eastern Telegraph Company's Exhibits at Vienna, 399.
Edison Lamp, Molecular Radiation in, by Dr. Fleming, 65.
Edison's System:—
at Holborn Restaurant, 161.
on Holborn-viaduct, 232.
on ss. "Oregon," 463.
in New Town Hall, Paris, 571.
at Vienna Exhibition, 447.
Edison-Hopkinson Dynamo, Report on, 296.
Edison-Hopkinson Dynamo, 546.
Edison and Swan Companies, Amalgamation of (Leading Article), 492.
Education, Technical, in Nottingham, 445.
Electric Arc, Resistance of, by O. Frolich, 150.
Electric Discharge with Chloride of Silver Battery, by W. de la Rue and Dr. Muller, 133.
Electric Light:—
Companies, The Survival of the Fittest, 564.
Discovery of, 162.
Fire Risks and, by K. Hedges, 474.
at the Leeds Festival, 535.
on ss. "Oregon," 463.
in new Town Hall, Paris, 571.
Electric Lighting:—
Act, T. H. Blakesley's Pamphlet on, 425.
Cheap Installations (Leading Article), 132.
Cost of compared with Gas, 235, 248.
and Gas, 259.
Development of, by J. E. H. Gordon, 137.
Examination Paper set by Prof. Ayrton, of City and Guilds Institute, 106.
Fire Risks of, by K. Hedges, 474.
at the Fisheries Exhibition, 164, 201.
Prof. Fleeming Jenkin's Report on, 114.
v. Gas in South Wales Iron Works, 163.
Guarding against Monopolies (Leading Article), 348.
Holborn Restaurant Installation, 161.
of Holborn-viaduct, 232.
of Leeds, 43, 71.
for Mines (Leading Article), 108.
at the Pavilion, Brighton, 175.
Practical Notes on Interior Lighting, 282.
The Provisional Orders (Leading Article), 228.
at the Reform Club, 37.
Select Committee and the Provisional Orders (Leading Article), 276.
Select Committee on Provisional Orders, Evidence given Before, 277.
Tender to Newington Vestry, 83.
Water Power for, 428.
Electric, Motors (*see* MOTORS).
Electric Telegraphy (*see* TELEGRAPHY).
Electric Tramways (*see* TRAMWAYS).
Electrical Instrument Making, Paper set at City and Guilds Institute Examination, 106.
Electrical Thought, Grooves in (Leading Article), 444.
Electrical Units and Standards (*see* UNITS).
Electricity, Animal, Galvani and, by Prof. M'Kendrick, 472.
Electricity at the Board of Trade, 425.
Electricity, Elementary, 9, 30, 55, 78, 102, 174, 485, 534.
Electricity, Application of, to the Working of Coal Mines, 272.
Electricity and Magnetism, Science and Art Department's Examination Paper on, 250.
Electricity and Physiology, 320.

Electricity, Atmospheric, at Pike's Peak, 602.
Electricity in Campos, 340.
Electricity, Execution by Means of, 314.
Electricity and the Fire Brigade, 604.
Electricity *v.* Gas, 124, 125.
Electricity as a Motive Power, Edison's Opinions on, 196, 219.
Electricity, Novel Application of, to Mining, 604.

NOTES (*continued*):
Electricity and Photography, 411.
Electricity, Statical, Dvorak's Experiments, 436.
Electricity, Supply of by Local Authorities, 173.
Electricity in the Tornado, 578.
Electricity and Vegetation, 411.
Electro-Amalgamator Co., to be Wound Up, 481.
Electrodes, the Flexion of Polarised, 97.
Electro-Dynamometer for Alternate Currents, 362.
Electrolysis of Various Solutions, Bartoli's and Papasogli's Experiments, 28, 101.
Electrolysis, Semmola's New Experiments in, 27.
Electro-magnet and Ophthalmic Surgery, 409.
Electro-magnets, Ayrton and Perry on the Winding of, 100.
Electro-magnetism, the Discovery of, 171.
Electrophones, Maiche's, 529.
Electroplating, The case of the Plating Company *v.* Farquharson and others, 4.
Energy, Electrical Transmission of (*see* POWER).
Execution by means of Electricity, 314.
Exhibitions:—
Cincinnati, 313.
Fisheries, 49, 97, 315, 338, 458, 553, 577.
Metal Trades, 197.
Philadelphia, 483.
the Reporting of by Newspapers, 217.
Turin, 505.
Vienna, 3, 27, 74, 98, 172, 193, 196, 219, 242, 265, 314, 338, 458, 481, 505, 601.
Fancy Fair, a Novel Idea, 50.
Farrer, T. H., made a Baronet, 529.
Faure Accumulator Company, Mr. Turner's Circular, 26.
Fire Alarms in Hotels, Edison's, 458.
Fire Alarms in Nottingham, 482.
Fire on the "Dandolo," 289.
Fire at Edison New York Station, 385.
Fire Brigade, Electricity and, 604.
Fisheries Exhibition (*see* EXHIBITIONS).
Flame, Electric Action of, 436.
Foochow, Telegraph Station Opened at, 121.
Fox, St. G. Lane, His Patent for Secondary Batteries, 77.
French Telegraphs, 531.
Gas and Electricity, 124, 125.
Gas and Electricity, a Compromise, 218.
Gas, Reduction of Price in London, 170.
Gaulard and Gibbs' System on the Metropolitan Railway, 410.
Geodetic Congress, International, at Rome, 338, 553.
German Telegraphs, Battery Expenses of, 169, 266.
German Union Telegraph Co., a Relay Station established at Lowestoft, 530.
Gilchrist Scholarship at University College, 338, 553.
Glasgow College of Science, 26, 362.
Glasgow Town Council and Electric Lighting, 388.
Glass, Tempering and the Resistance of, 27, 99.
Gramme Electrical Co., Patents Controlled by, 265.
Gramme Patent, Alleged Infringement of, 361, 435.
Gramme Patents, Lord Bury on, 266.
Great Northern Telegraph Co., Duplication of its Cables, 482.
Great Western Electric Light Co., Capital to be Reduced, 2.
Griscom Motor, The, 389.
Hall's Phenomena, 460.
Hammond Electric Light Co., Circular issued by, 339.
Hartley, F. W., his Photometer, 76.
Hedges, K., Supply of Electricity by Local Authorities, 173.
Herz *v.* Van Rysselberghe, 434.
Hittorf's Experiments on Luminosity, 241.
Holborn Restaurant, The, 555.
Hospitals and the Telephone, 169.
Huxley, Prof., Elected President of Royal Society, 193.
Incandescent Lamp Carbons, the case of Weston *v.* Sawyer and Mann, 457.
Incandescent Lamps:—
Boulton, Soward, and Probert's, 171.
Brush's Shield for, 26.
Carbon Deposits in, 603.
in Mines, 577.
India Rubber, New Source of, 361.
Induction, Quet's Experiments on, 410.
Information Wanted:—
Re D'Or's Lamp and Battery, 122.
Institution of Civil Engineers, 603.
Insulating Compound, Torr and Winfield's New, 99.

NOTES (*continued*):
Insulator, an Incombustible, 170.
Insulator for Wires, New, 361.
"International," ss., leaves with Spanish National Cables, 433, 506.
International Telegraph Convention, Siamese Government joins the, 97.
Interrupter, Budde's, 482.
Iridium, Hittorf's Experiments with, 241.
Iron, the Coating of with Zinc, 194.
Jablochkoff Co., Petition for Winding-up of, 553, 601.
Johnson and Phillips, Mr. Pell associated with, 74.
Joke, A, 577.
Journalism, The Telegraph and, 218, 244.
Journals, Electrical, New, 97, 505.
Kabath's Accumulators, 436.
L'Aborde, Death of M. l'Abbé, 100.
Lancashire Maxim-Weston Co.'s Tender to Liverpool Corporation, 603.
Lane-Fox Lamps in Melbourne House of Parliament, 314.
Lane-Fox Patent for Secondary Batteries, 77.
Launches, Electric:—
Clark's at Glasgow, 410.
at Vienna, 458.
Leyden Jar, Discharge of, Dvorak's Experiments, 436.
Licenses, Letter from Board of Trade *re*, 341.
Licenses under Electric Lighting Act, Applications for, 1, 25, 266.
Liege University, Diploma of Electrical Engineer at, 289, 316.
Light, The Dispersion of, 555.
Lighthouses, Electric Lights for, 98, 361, 505.
Lighthouses, The Illumination Question, 122, 148.
Lightning:—
Aborescent Markings on People Struck (Roy. Soc., Ed.), 172.
Descending a Coal Mine, 338.
M. Colladon on Protection from, 459.
Dynamite Struck by, 315.
Flashes, Duration and Brightness of, 269.
Foretelling the Approach of Storms by, 99.
Globular, 50.
Lighthouse Destroyed by, 433.
Numerous Deaths from in America, 433.
Oil Tanks fired by, 3.
in Panama, 388.
Colonel Parnell on Defence against, 220.
Photographing it, 457.
Powder Magazine fired by, 97.
Protecting Oil Tanks from, 458.
and Telegraph Wires, 529.
Effect of on Trees, 340.
Various Accidents by, 123, 147, 217, 220, 241, 242, 313, 362, 385, 433, 459, 553.
Water Pipes Broken by, 506.
Lightships, Telegraphic Communication with, 265.
Local Authorities and the Supply of Electricity, 173.
Locomotive, the First Electric, 267.
Locomotives, An Electric Headlight for, 314.
London and Globe *v.* United Telephone Co., the Wire Cutting Case, 4, 28, 51, 290.
London and Globe and United Telephone Companies, *re* the Hunnings Transmitter, 122.

THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

No. 1.—Vol. XI. SATURDAY, MAY 19, 1883. Price 4d.

NOTES.

Electric Lighting in Boston (America).—It is stated that the city of Boston intend to spend 83,000 dollars in electric lighting this year.

Postal Telegraph Appointment.—Mr. J. Clarke, sorting clerk and telegraphist at Winchester, has been appointed postmaster of Basingstoke.

Cricket.—On Whit Monday Messrs. Siemens Brothers played R. E. Crompton and Company at cricket, and the latter won by one innings and 108 runs.

Provisional Order Abandoned.—The Metropolitan Brush Electric Light Company have abandoned their Provisional Order for Camberwell and Penge.

Electric Light Wires in Pittsburgh, U.S.—The Fire Marshal of Pittsburgh has inspected the electric light wires in that city, and reported them to be perfectly safe.

The Telephone in Paris.—The Western Railway Company of France have just connected their termini at Saint-Lazare and Montparnasse with the chief municipal offices of Paris.

The Edison System in Baltimore.—The offices of the *Sun* newspaper in Baltimore, U.S., are lighted by Edison's incandescent system. In a recent issue this paper speaks in high terms of the lights.

Anglo-American Brush Corporation.—Lord Thurlow has accepted the chairmanship of this corporation, and Mr. Herbert C. Gibbs, of the firm of Messrs. Antony Gibbs and Sons, has also joined the board.

Lewisham.—The Metropolitan Brush Company have withdrawn their application to light the district of Lewisham, but have expressed a hope that the district board of works will grant them permission to do so next year.

Electric Lighting for Lambeth.—The Lambeth Vestry have given notice of their intention to apply, under the Electric Lighting Act, for a license "to construct and maintain electric lines and works and to supply electricity within the parish."

The Zanzibar and Mozambique Cable.—The Eastern Telegraph Company announce the repair of the Eastern and South African Telegraph Company's cable between Zanzibar and Mozambique, thus re-establishing telegraphic communication with the Cape of Good Hope and Natal.

Society of Telegraph Engineers.—The next meeting will take place at 8 p.m. on Thursday, the 24th inst., at 25, Great George-street, S.W., when the following paper will be read:—"On the Cause of Magnetism" (illustrated by experiments). By Professor D. E. Hughes, F.R.S., vice-president.

Electric Lighting for Westminster.—The Electric Lighting Committee of the St. James's (Westminster) Vestry have recommended that the Edison Company should light the whole of the parish, it being desirable that there should be no conflicting interests between different companies. This recommendation has been adopted by the vestry.

A Change of Title.—We notice that our contemporary *Electric Light* has changed hands, and that its new proprietors have thought fit to alter its title to that of *The Electrical Engineer.* Concurrently with this change we notice that the price of each issue has been reduced from 6d. to 3d. We wish our contemporary all success and a prosperous life.

The Submarine Cables Trust.—With £1,837 brought down, the revenue of the Submarine Cables Trust for the year was £23,901, out of which the expenses of the Trust for that period, amounting to £1,333, and two half-yearly coupons at the usual rate of 6 per cent. per annum, absorbing £20,382, have been paid. The sum left to be carried forward is £2,185.

The Scandinavian Electric Company.—Mr. J. E. Costello, the liquidator of this company, has given notice to the effect that the affairs of the company being now fully wound up, a general meeting will be held on the 15th June, at 12 noon, at 20, Bucklersbury, E.C., when an account will be submitted showing the manner in which such winding-up has been conducted.

Appointment.—Mr. Hugo Pischon, who in 1874 introduced the Pintsch system of lighting railway carriages and steam ships into England, and who remained for some years managing director of the Pintsch Patent Lighting Company in London, has been appointed assistant managing director by the German Edison Company of Berlin, which has been lately established.

Hygienic Exhibition in Berlin.—This exhibition was opened on Thursday, 10th May. It is lighted by electric light, and both telegraph and telephone offices are to be found in the building. Siemens arc lamps illuminate the square in front of the building, whilst a large concert hall inside is lighted by Edison's system. A model coal mine is also lighted up by Siemens and Halske arc lamps.

The "Operator."—The *Operator* of New York, which lately assumed the sub-title of *Electrical World* in addition, has now reverted to its old and original title, whilst the *Electrical World* has been launched as a separate paper. The *Operator* will be devoted, as in its earlier days, exclusively to telegraphy, whilst the *Electrical World* will have a wider scope. The latter will appear weekly, but the former bi-monthly only.

The Telephone in Sheerness Dockyard.—It has been

Digitized by Google

decided by the authorities of Sheerness Yard to establish telephonic communication between the bell stand and the ticket office, so that immediately the bell is rung for the last time the issue of tickets will be suspended, and those who have not passed through the office, even although they may have entered the dockyard gates, will have an eighth deducted from their day's pay.

Opera by Telephone.—An interesting experiment was tried the other evening by the management of the Savoy Theatre for the amusement of the Prince of Wales and other guests of Mr. Arthur Sullivan. A special wire having been laid on to Mr. Sullivan's private residence, Queen's Mansions, the principal songs and choruses of "Iolanthe" were sung upon the stage by Miss Barnett, Mr. Rutland Barrington, Mr. Temple, and transmitted by telephone.

Prevention of Fires.—A public meeting will be held at the Society of Arts on the subject of the prevention of fires in theatres. The report of a committee of the society, which has for some time been investigating the question, will be brought before this meeting for its consideration. The precise date has not yet been decided, but it will be held the end of the present month. Further particulars will appear in future numbers of the Society of Arts' *Journal*.

Oriental Telephone Company.—Subject to final audit, the directors of this company will, at the annual general meeting to be held on the 30th inst., after carrying £7,000 to reserve fund, and replacing to capital the outlay on exchanges sold, recommend a final dividend of 2½ per cent., making, with the interim dividend already paid, a total distribution of 5 per cent. for the year ending December 31, 1882. The sum of £709 4s. 8d. is carried forward.

Electric Lighting at Chesterfield.—The Committee of the Chesterfield Town Council, appointed to consider the electric lighting arrangements in the town, which have now been in existence for some time past, have reported that the lighting of the streets has been completed to their satisfaction. In accordance with this report the town council have decided to enter into a permanent contract with the Hammond Electric Light Company, by whom the work has been carried out.

Great Western Electric Light Company.—A notice appeared in the *London Gazette* of May 1, to the following effect:—"A petition for confirming a resolution reducing the capital of the above company from £250,000 to £195,000, was, on the 3rd day of May, 1883, presented to Her Majesty's High Court of Justice, and is now pending, and the list of creditors of the company is to be made out as for the 15th day of June, 1883." The notice is signed by Messrs. Ashurst, Morris, Crisp, and Co., 6, Old-jewry, E.C., solicitors for the company.

Bootle Town Council and Electric Lighting.—The Town Council of Bootle, near Liverpool, some time since appointed a committee to visit the works of the Electric Carbon Storage and Apparatus Manufacturing Company of Scotland. This committee presented their report at a meeting of the council held last week. They suggested that, if the council entertained the matter at all, the company should be allowed to submit an estimate for lighting the Town Hall. After a little discussion the report was accepted, and the matter postponed.

The Telephone in Buenos Ayres.—We recently announced that the rival telephone companies in Buenos Ayres had decided to join hands. Since then the United Telephone Company of the Rio de la Plata, as the combined interests are now called, has issued the first list of subscribers to its Buenos Ayres Exchange. It appears that these already numbered close on to 1,000 on the 1st of April, and that the rate of increase is very large. The company have just received a large instalment of telephone cables and exchange apparatus, and seem to be going ahead.

Electric Lighting in Bombay.—The shop of Messrs. Treacher and Co. in Bombay has been lighted on the incandescent system by the Eastern Electric Light and Power Company. Fifty Swan lamps are used, the current being supplied by twenty accumulators. The same company have contracted with the Government to light the High Court, the Esplanade, the band stand, and several roads in the city. The company's charging stations are at Mody Bay and Tardes, and their work is being carried out under the superintendence of Major Strutt, managing director, and Mr. Grindle, electrician.

Telegraph Materials and Instruments Wanted.—The Caledonian Railway Company are inviting tenders for the supply of india rubber, iron wire and strand (galvanised), signal fittings, telegraph instruments, &c., for twelve months from the 1st of July next. Specifications and forms of tender, and any other necessary information, may be obtained from Mr. William Haig, superintendent of stores, Caledonian Railway, St. Rollox, Glasgow. Patterns may be inspected from 9 a.m. till 5 p.m., at the Stores. Tenders, endorsed "Tender for Stores," to be lodged with the Secretary, 302, Buchanan-street, Glasgow, not later than 28th inst.

The Maxim-Weston Electric Company.—A correspondent has kindly forwarded to us a circular relating to this company, signed by Hugh Watt. It is extremely difficult to criticise a managing director's figures, but at the same time it is singular to find a company said to be making £200 a week profit anxious to issue fresh capital under the conditions put forward at the recent meeting. We should have thought that under such circumstances money would have been only too easily obtained. We have heard that the reorganisation mentioned in this circular has consisted in getting rid of most of the men who knew anything of their work.

The Paris International Electrical Congress.—Professors Trowbridge, of Cambridge, Mass., Rowland, of Baltimore, and Barker, of Philadelphia, visited the Department of State at Washington on the 19th April, to arrange the details of the electrical experiments to be conducted on the part of the United States with reference to the international conference to be held at Paris next October. It was arranged, says the *Electrical World* of New York, that Professor Rowland should conduct the experiments to determine the standard of electrical resistance, Professor Trowbridge the experiments relating to atmospheric electrical disturbances, and Professor Barker those which look to the determination of a standard of light.

Leeds and the Electric Light.—It is understood that the experimental lighting authorised at their last meeting by the Leeds Town Council will embrace the lighting of the Victoria Hall and vestibule, and the erection of arc lamps in Victoria-square; also the lighting of certain portions of the new Public Offices, namely, the office on the ground floor where all the rates and rents due to the corporation will be paid, the large clerks' room adjoining, the lending library, the reference library, and the reading room; and the placing of arc lamps in front of the offices in Calverley-street. It is probable that the shed in the new fire brigade station will be utilised for the engine and dynamos. The intention is, we believe, to invite tenders for the work.

Female Telegraphists in Ireland.—In the House of

Digitized by Google

Commons, on Thursday, May 10, Mr. Kenny asked the Postmaster-General whether it was a fact that the female telegraph clerks attached to the Dundalk office were required to perform the entire of the telegraph Sunday duty of that office, in addition to the limit of 48 hours per week, as laid down by his late revision; and, if so, whether any compensation had been allowed for this extra duty. Mr. Fawcett said: "In reply to the hon. member I have ascertained that the two female telegraphists employed at the Dundalk office work during the six week days the usual time of 48 hours. In addition to this each of them works two hours on each alternative Sunday. They are entitled to extra pay to the extent of two hours a fortnight, and I have given instructions that the amount due to them shall be paid. The night work is done entirely by the male staff."

Bradford Provisional Order.—At the last meeting of the Bradford (Yorks.) Town Council the town clerk reported that the officers of the Board of Trade had invited him and the parliamentary agent and the electrical engineer of the corporation to a conference on the points connected with the Bradford Provisional Order, on which the board and the corporation differed; that a conference had accordingly been held, resulting in a satisfactory arrangement; that the area within which the corporation are to exercise their powers within two years was limited to Market-street, Bank-street, and Darley-street; that power was given to the corporation from time to time to determine by resolution to what other districts they would extend their operations, without application to the Board of Trade, and that the board had determined to adopt the Bradford order as the model for other Corporation Provisional Orders. A member of the council stated that for this gratifying result they were indebted to their town clerk.

Oil Tanks Fired by Lightning.—The following telegram appeared in the *Standard* of Friday, the 11th inst. It was dated New York, Thursday night (May 10), and stated that: "During a storm to-day (Thursday) the lightning struck and set fire to a wood factory in the midst of a dense tenement-house population adjoining the Belle Vue Hospital in Jersey City. For a short time the excitement was intense, but the amount of damage was small. Another flash did more damage. It struck the Standard Oil Company's works in Jersey City, and a huge iron tank exploded with a violence which shook the earth for a long distance. The flame which immediately rose was seen twenty-four miles off. Ponderous fragments of the tank were thrown a distance of half a mile, and the crowds who assembled on the top of a neighbouring hill a mile away were scorched. The blazing fluid poured in a great stream towards the river, and on its way ignited other tanks. The workmen and firemen ordered to retreat before this sudden foe started upon a fearful race; their hair and clothing were singed, and the six who were most in the rear were overwhelmed. It is feared that other fatalities have occurred. The destruction has involved eighteen tanks of crude oil and two of naphtha, each averaging, perhaps, ten thousand barrels. The works, which covered twenty acres, also contained many thousand barrels of refined oil. The loss is variously estimated at sums all of which approach one million dollars."

A Cable for Sale.—Tokenhouse-yard is to witness a remarkable lot under the hammer on the 22nd inst., and from the fact that it lies electrically inert at the bottom of "the deep blue sea," and may have served the mermaids for a skipping rope, or possibly a crinoline, to say nothing of what uses Father Neptune has found for it, Mr. George Robins, of immortal memory, would have had a subject to his own heart for giving reins to the pleasures of the imagination, were he alive to handle the hammer in connection with such a novel subject of competition. The lot in question is none other than a submarine telegraph cable extending from Para, in Brazil, to Cayenne, in French Guiana, and to Georgetown, in British Guiana. There is something delightfully speculative about this prospect of investment beneath the foaming billows, especially as the Court of Chancery, with a fine regard for fairness, only promise to secure to the purchaser the cable as it now actually exists, while the particulars expressly set forth that it has not been for some time in use. Moreover, with a delicious frankness—for whenever was a house announced to have had its drainage out of order, or smokey chimneys when last occupied?—this mysterious link beneath the ocean wave "is believed to have been defective when last used." Those who assemble at the Mart to see what bold investor in submarine telegraphy will be forthcoming, might, it is certain, wend their way to Tokenhouse-yard for an indefinite period before they again have particulars of sale brought under their notice containing so little in the way of piling on the agony in florid description of possible advantages.—*City Press.*

Electric Lighting in Theatres.—We take the following account of some recent experiments at the Opera House, Vienna, from a Viennese paper. They were carried out in the presence of a large audience, who had been specially invited for the occasion. The installation consisted of 1,236 incandescent lamps fed by two hundred accumulators, the latter being supplied by the Electrical Power Storage Company, of London, and was put up by the Anglo-Austrian Electrical Company. The first scene showed a room in which broad daylight, produced by white lights, gradually turned into night with the aid of the whole of the lights. After this experiment, which went off with surprising steadiness, the audience broke out into loud applause. Great interest was excited by the carrying of a candelabrum across the stage. The light was made to follow the same with a marvellous likeness to nature, and the effect of blowing out first one candle and then the other, and subsequently relighting them, was very highly appreciated, as showing a complete command over the whole or partial illumination of the stage. After further experiments came a trial of costumes. About fifty "supers," male and female, crowded the stage—monks, pages, knights, hussars, priestesses, Egyptians, ballet dancers, &c., in dresses of motley make and hue. The light showed up the costumes perfectly clearly, without the materials losing any of their brightness or gloss. After this trial the scene was changed, and experiments followed with landscape scenes. Bright daylight gradually changed to moonlight, succeeded by sunrise, deepening to morning glow; this lighting began at the cross battens, then flies, battens, and footlights, followed by a thunderstorm, with lightning. All these experiments went off without a hitch, and with the most perfectly equable distribution of light, obtaining the congratulations of all present, including several leading Viennese experts.

Vienna Electrical Exhibition.—We have received from the Science and Art Department a copy of a recent decree of the Austrian Minister for Commerce, having reference to the protection of patented machines, &c., during the course of the exhibition. The conditions laid down are as follow:—1. Applications for certificate of protection to be made as soon as possible by owners of objects or by accredited agents, and to be accompanied by the necessary plans, drawings, and duplicates, together with the authorisation for the agent to act. [These applications and requests

Digitized by Google

for more detailed information must be addressed to the Privilegien Department for the Imperial Ministry of Commerce, Vienna.] 2. Before request is considered exhibitors must state whether necessary formalities have been complied with and make certain other declarations. The objects will afterwards be examined and reported on. 3. Certificates will be issued conjointly by the Ministry of Commerce and the Hungarian Minister of Agriculture and will take effect from date of entry to 31st December, 1883. 4. Certificates will be made out in annexed form, and arbitrators will decide disputed points. 5. No complaints of the refusal to grant a certificate will be considered by the Government departments. If the legality of such decision is questioned the matter is to go to the arbitrators. 6. Complaints will not be dealt with by the department, but referred to the arbitrators, and questions of misdescription will be treated in accordance with Rule 4. 7. The certificates of protection issued will be published in the *Austro-Hungarian Gazette*. The decision in contingencies not provided for is vested in the Minister of Commerce.—From information received from Vienna we gather that it is the intention of the organising committee to fix an arc lamp of 20,000 candle-power in the topmost, or lantern-gallery, of the Rotunda, where the exhibition is to be held; the light from this lamp will be deflected by means of reflectors. Another gallery below this is to be wreathed with twenty-eight arc lamps of from 2,000 to 3,000 candle-power, whilst on another and larger gallery yet further below will be placed 112 arc lamps of about 1,000 candle-power each. The ground floor of the building will also be lighted by numerous arc lamps, whilst the transepts, galleries, and courts will be brilliantly illuminated by incandescent lamps. Powerful search lights will be fitted on the outside of the building, the light from which will be thrown on to distant objects, such as notable buildings, &c.

Injuring Telephone Wires in London.—At the Guildhall police-court on Wednesday Theodore Torry, manager at the Globe Telephone Company, and William Goodfellow and James Molyneux, two men working under him, were charged by the United Telephone Company, before Alderman Stone, for wilfully and maliciously injuring their wires. Mr. J. P. Grain appeared for the complainants; and Mr. George Lewis for the Globe Company, to defend the men. Mr. Grain said that he was proceeding under the 27th section of the Malicious Damage to Property Act, by which any person being found guilty was deemed guilty of a misdemeanour, and was liable to imprisonment not exceeding two years, with or without hard labour. The United Telephone Company had a large number of subscribers, and enjoyed a large revenue. That company being successful, the owners of the invention worked by the company started the Globe Company in opposition to them, and hence the conduct of the workmen towards the complainant company. The course they adopted was to tie their wires together with other wire, so that when a current of electricity went through one of them, instead of setting one bell ringing, it would set forty ringing at once. The company, when they got permission to work the patent, made arrangements with the authorities of Weavers' Hall to have two poles placed on the roof of the hall, to which they could convey their wires from their office, and thence to their different customers. One of their lines passed over the Wool Exchange, in Coleman-street, where the Globe Company had offices. They put on the roof of that building, to carry their wires to other points, what was termed a derrick; but the wires of the United Company did not interfere with the wires of the Globe Company; yet, notwithstanding that, they tied up the wires of the United Telephone Company and put them all in confusion.—James Reynolds, 36, Brook-road, Upper Holloway, labourer, said that in the beginning of May he was in the service of the Globe Company. On the 1st of May he was on the top of the Wool Exchange running wires for the Globe, and Molyneux and Goodfellow were there also. Torry was on the roof during the greater part of the time, giving orders, witness believed. Molyneux was his foreman. In consequence of orders received, Molyneux on one occasion tied the wires up with another wire in three places. That was on Wednesday, the 2nd of May, and a current of electricity was then put on and connected from the wires of the United with the battery room of the Globe. That would cause a ringing of the bells of the subscribers, and the men had a laugh about it on the roof, as they knew what the result would be. He also gave evidence as to other acts in which the wires had been tied up. Mr. Lewis cross-examined the witness as to his knowledge with regard to who gave the order for what was done, and who was responsible for it. Upon the adjournment of the inquiry Mr. Lewis complained that Mr. Grain had made statements under instructions which circumstances would not justify. The two companies were in litigation in chancery, and had already spent £30,000 in law costs. He said the case ought not to have been brought before that court, but before the Court of Chancery. The further hearing was then adjourned.

Legal Decision as to Electro-Plating Patents.—The case of the Plating Company (Limited), appellants, and Farquharson and others, respondents, came before the House of Lords recently, and we may conclude that their decision has settled this long contended suit. There were present—The Lord Chancellor, Lord Watson, and Lord Fitzgerald. The appellants appealed against the judgment of the Court of Appeal, which was against them. In giving judgment the Lord Chancellor said:—"I agree with the Court of Appeal in considering that the respondents' solution is, in fact, prepared in a manner substantially different from the method described in the appellants' specification. The bath which the respondents use for the process of deposition is prepared by dissolving in water a crystallised salt, prepared and sold by Mr. William Elmore, whose evidence appears to me to be worthy of credit. The appellants themselves have also, for some time, bought and used the same salts of Mr. Elmore's manufacture, and it is noticeable that they have not gone into any evidence for the purpose of showing that the chemical composition of these salts is identical with that of the salts manufactured in the way described in their specification. The preparation of these salts (used by the respondents), according to Mr. Elmore's evidence, is conducted by an extremely simple process. The electricity in the respondents' process is generated by a dynamo electric machine, and not by a battery, and it appears from the evidence of the appellants' witness, Brooks, that a dynamo electric machine as ordinarily used, though producing a current many times stronger than Smee's or Grove's batteries, is not found to cause ammonia to be evolved from the bath. While the respondents' solution is made from crystallised salts by two perfectly simple operations—the second to be repeated only if the salt is very acid after the first crystallising—the method of preparing the patentees' solution, described in the specification, requires seven distinct operations, of which the first three are apparently the most important—being entirely occupied in the preparation of a dry anhydrous sulphate of nickel without the use of nitric acid—by an elaborate process, requiring the application of regulated heat, in a manner wholly different from that in which the respondents' crystal-

Digitized by Google

lised sulphate of nickel is obtained, and the purpose of these successive operations is to eliminate, in that stage, those impurities which by the respondents' method are thrown off into the mother liquor, when the double sulphate crystallises after the two mixed sulphates have been dissolved and boiled. These differences are the more important when it is borne in mind the use, for the electro-deposition of nickel, of the double sulphate of nickel and ammonia was confessedly not new, and that all which the patentee proposed to do was 'to adopt process in the preparation of the solutions,' and to 'observe precautions,' which might obviate the defects in the previous modes of preparing them and get rid of impurities which the previous modes had failed to remove. The result is that there is, in my judgment, no infringement of the patent as limited by the disclaimer. The products of deposition are not patented; nothing is, in fact, patented but the one particular method described in the specification of preparing the solutions of the double sulphates which the appellants or Brooks formerly used, but do not, apparently, now use, and the solution used by the respondents is prepared in a substantially different way. I therefore move your lordships to dismiss this appeal with costs." Lords Watson and Fitzgerald concurred, and the order appealed from was affirmed, and the appeal dismissed with costs.

Electric Lighting in the House of Commons.—On Thursday (May 10), on the House going into Committee of of Supply on the Civil Service Estimates, the following not very creditable discussion arose with reference to the lighting of the dining room by the Edison Company. We borrow our account of the proceedings from the report furnished to a daily contemporary. It appears that the matter was first brought to notice by Mr. Gorst, who complained of the varying brilliancy of the electric light in the reading room of the House, and asked whether any other than the Edison Company had been invited to tender for the lighting, and whether tenders would be invited from other companies before the electric light was used in other parts of the building.—Mr. S. Lefevre explained that, as a proposition had been made to him by the Edison Company to light the dining rooms and library of the House experimentally for a very small sum, he had thought it desirable that members should see what the effect would be. It did not appear to him that electric lighting in its present stage was a proper subject for competition. When arranging for the lighting of the Law Courts he had considered the whole subject, and had come to the conclusion that he could not invite competition. It appeared to him to be the best plan to select the system he thought most likely to answer. He came to the conclusion that the Swan light was best adapted to the Law Courts. Between the Swan and the Edison he saw little difference. As he gave the preference to one in the the case of the Law Courts it appeared to him not unreasonable to try the Edison in that House. Whether it would be ultimately adopted he could not say. He would consult the comfort and wishes of hon. members.—Lord R. Churchill repudiated a suggestion by Mr. Lefevre that he might be interested in the Swan or any other company; but the Swan Company had lit the Law Courts in a manner which had satisfied everybody, and had made almost superhuman exertions to get the lighting in the Law Courts ready for the Royal opening, and they certainly on this account deserved some notice from the First Commissioner of Works. The complaint of the other companies was that without saying a word to any of them the Office of Works concluded an arrangement with this Yankee adventurer, who was shrewdly suspected of having stolen the patent of Mr. Swan himself, and had let him light the House of Commons, which was, without exception, the greatest advertisement they could possibly give to an electric lighting company. It was now known all over the world, wherever there was a parliamentary assembly, that the Edison Company were lighting the House of Commons. Though he was not interested in these companies there were directors of the Edison Company in the House, and the right hon. baronet, the member for the University of London, was the principal director of the Edison Company. Mr. Bouverie, a great supporter of the Whig party, was a member of the Edison Company; and it was, he believed, notorious—and if not a fact it should be easily disproved—that Mr. Preece, the electrician of the Post Office, was a large shareholder in that company. It was important that where electric lighting was the subject of the most tremendous speculation on the Stock Exchange any Government official who thought it right to introduce electric lighting into public buildings should take the utmost care that there should not be the slightest advantage given to one company over another. The Edison Company had already had the trial, which the First Commissioner said they ought to have, at the Post Office. He had no right to give the advantage over an English company to an American adventurer who had obtained a patent by extraordinary and questionable ways, and, he believed, never took out a patent until Mr. Swan disclosed his patent. He hoped before the Government concluded any further arrangements with this most adventurous company the First Commissioner would put everything with respect to the lighting of the House or public buildings up to tender, reserving to himself, of course, the right of ultimate selection.—Mr. S. Lefevre was sorry if he had done the noble lord any injustice, but his speeches on this subject appeared to him to have been directed not from the point of view of the interests of the public and of economy, but in the interests of some rival company to that which had been lighting the House. There was not a word that had been said against the selection of the Edison Company to light the House that was not equally applicable to his selection of the Swan Company at an earlier date to light the Law Courts. The Edison Company laid before him certain reasons, upon which he was satisfied that their system was best adapted to the House at the time. For one thing, they had, and were the only company who had, a noiseless dynamo—(Lord R. Churchill: "No")—and it was a great object that the process of lighting that House should be accomplished without noise. But the difference between the Swan and the Edison systems was so small that on the whole he thought it not unreasonable to give the Edison system a trial. As to its belonging to an American adventurer, that he thought was a very unfair representation. Mr. Edison was one of the most distinguished scientific men of the day, and was beyond all suspicion of the character mentioned by his noble friend. The company formed in England was of a highly respectable character, presided over by Mr. Bouverie, who, the noble lord insinuated, was a political supporter of the Government. When the contract was made no considerations of that sort had any weight with the Office of Works.—Mr. O'Donnell said it was strange that the Swan Company, having done well in the Law Courts, were not allowed to try the House of Commons also.—With reference to Lord R. Churchill's remarks, Mr. Arnold White, the secretary of the London Edison Company, writes in *The Times* of the 14th inst. warmly defending Mr. Edison, and stating that Mr. Preece's name is not on the register of shareholders of the Edison Company.

DR. NORVIN GREEN.

It will be remembered that in our issue of May 5th we reported the welcome given by the Atlantic cable companies to Dr. Norvin Green, the president of the Western Union Telegraph Company of the United States. The telegraphic system of America is the outcome of private enterprise, and has not yet been nor does it seem likely just at present to be taken under State control. The Western Union Company's system is *the* telegraphic system of America, and hence the president of the company has a somewhat corresponding position there to that of Mr. Fawcett here.

We have great pleasure in giving this week a portrait of the gentleman to whom the welcome we have referred to was extended, and we intend to give in our next issue but one a portrait of Mr. John Pender, M.P., who so ably presided on the occasion.

A brief history of the Western Union Company will be found in that excellent work—a work which, unfortunately, in this country of Cooke and Wheatstone, has no counterpart—"The Telegraph in America; its Founders, Promoters, and Noted Men," by James D. Reid. Like other comprehensive telegraph systems, this great company resulted from the amalgamation of smaller companies, and it is a living proof that telegraphy must ultimately and necessarily be, in any given district, a monopoly. Competition has its uses—and very good uses too—to a point when competition becomes costly, and tends to retard instead of to accelerate telegraphic traffic. We may quote, in connection with this statement, the last paragraph of chap. 35 and the first paragraph in chap. 36 of Reid's book, which are as follow:—

Dr. NORVIN GREEN.

"Among other incidents which prefaced the morning, which, after a time, came flushed with the rosy light of a brighter day, was one significant enough to remember. One stormy night Wade and Stager met by accident at an eating counter in Selby, Ohio. Neither of them was in the condition of ordering a square meal. Hunger drew them together and made them communicative. Wade acknowledged over his pork and beans that he was making nothing, and told Stager to stop whistling and confess. Stager thus appealed to rested for a moment from his corn beef hash and acknowledged that the balances were on the wrong side. This led to a comparison of notes, and to a pretty clear evidence that the business was enough for one but starvation for two. Duplicate and triplicate rents and double force were eating up the entire income. It became a question with Wade whether to join the O'Reilly or the printing lines. It resulted in Wade's going to Rochester, a union of interests, an issue of 100,000dols. of bonds at 70 for a fresh effort, a general closing of all duplicate expenses, and success."

"One of the immediate results of the purchase lease and union of all the various interests, narrated in the preceding chapter, and their incorporation into the Western Union Telegraph Company, was the stoppage of numerous rents and the giving up of numerous choice corner offices, which had been hungrily seized upon at large prices in the contest for business. In this single direction an annual economy of over seventy thousand dollars was at once secured. It was soon felt, also, in a marked enlargement of business, a promptness it had never before reached. This was soon felt by those who most needed and relied upon its employment. Where answers to despatches of one day had been received, as a general rule, on the day following, these now came on the same day, sometimes in quick and gratifying response to the original message. Some messages were actually refused because the quickness of the response seemed incredible. It was like fresh blood to a system which, up to this time, had, in a great degree, failed to meet the expectations of the public. The well known card over the locked door of the office, 'gone to mend a break,' was no longer seen. Every thing had changed. The wires were steady, and full of business."

The views we have here illustrated are, we believe, quite in accordance with those pursued by the subject of our sketch. The following personal observations relating to Dr. Norvin Green are taken from the *Operator* of October 21, 1882:—

"Dr. Norvin Green was born in Kentucky, in 1818. He graduated in the Medical Department of the University of Louisville in 1840. Afterwards he served several terms in the Kentucky Legislature, with distinction, and in 1853 was appointed commissioner in charge of building a new custom house and post office in Louisville. In 1854 he became interested in telegraphy, and was soon made president of the South Western Telegraph Company. He was at that time a noted and popular man. Uniting good judgment and good sense with a decided ability as a stump speaker, and even ready to take a prominent part in the broad humours of a Kentucky barbecue, he was as much a popular favourite as he was a man held in high esteem by business men for his sagacity, firmness, and practical talent.

"After a career of brilliant success, under Dr. Green's vigorous and liberal administration, the South Western Telegraph Company fell into line with the general movement for consolidation, and was merged in the American Telegraph Company, which became in turn a constituent part of the Western Union. In recognition of the ability of Dr. Green he was thereupon made a vice-president of the Western Union, which position he filled, quietly and unostentatiously, but with extraordinary efficiency, until the death of President William Orton, whose successor he became by inevitable selection.

"The office of president of the Western Union Company requires a rare combination of qualifications. It has to deal with complicated legal and political problems, and is liable

Digitized by Google

to encounter difficulties from State legislation. The president must, therefore, not only have a thorough practical knowledge of the telegraphic system of the country, but he must have experience in public life and a knowledge of public men. It would be difficult to find a man possessed of these qualifications in the same degree as is Dr. Green. For more than a quarter of a century identified with telegraph management in responsible positions, he was long ago recognised as a man of statesmanlike breadth and attainment, and in 1869 was one of three candidates before the Kentucky Legislature for the United States Senate, on which occasion he was only defeated by a blunder of one of the caucus tellers, who, by mistake, counted a vote given for him as for a third candidate."

ON ELECTRIC STREET MAINS.

BY GISBERT KAPP.

There are two principal ways in which a district can be served with a direct supply of electricity from a central station. We can either lay down a heavy main line right through the middle of the district, and connect to it small branch leads which otherwise are not connected amongst themselves, or we can dispense with a heavy main line, and in its stead provide plenty of connections between all the different branch leads and between the station and some of the nearest branch leads.

In the first case, a positive lead is brought from the station to the far end of the main line, and from there brought back to that branch which is nearest the station. All the branches are connected to this returning positive lead and to a single negative lead, which goes from the station to the far end of the main line. Three leads are thus necessary, and a complication is thereby introduced, which at first sight may seem useless; but it is sometimes claimed for this system that when properly varying the potential at the station, in accordance with the demand for current in the district, all the branch leads can be kept at a fixed potential, no matter how fluctuating may be the consumption of current in different places. This system might aptly be called the *line of centres system*, for the main line is in reality nothing else than a succession of feeding centres for the branches.

The other system, where all the positive leads are connected among themselves in as many ways as possible, and the negative leads are similarly connected, might be called the *network system*.

In this arrangement the current is not made to flow along one definite route only, but, finding alternate ways open, it will naturally split up between the meshes of the network in such manner that the sum total of energy lost through resistance in the different circuits is a minimum. This, of course, is a very desirable result, but the drawback of the system is that the difference of potential near the station will be greater than that existing at distant points.

Considering the large amount of capital which must be laid down in mains if public and private lighting is to come into use, the question of selecting the best possible system is of great importance.

Whether one or the other, or a combination of both systems, should be employed must always depend upon the particular circumstances of the case, and, generally speaking, the necessary ramifications of a set of street mains are so complicated that a correct choice at first sight is not an easy matter.

If we reduce the two systems to their possible simplest forms, we find for the line of centres system an arrangement as per Fig. 1 or Fig. 2, and for the network system an arrangement as per Fig. 3. The arrangement shown in Fig. 1 has been described above; Fig. 2 is a modification of the same, the connections being made between the returning positive and outgoing negative lead on the one hand, and the returning negative and outgoing positive lead on the other hand. To distinguish the two arrangements, we will call Fig. 1 the single, and Fig. 2 the double line of centres system.

As regards Fig. 3, it might be objected that it does not in the least look like a network. Yet it is correct to classify it as such, for the best possible network is evidently that in which each circuit carries exactly the necessary amount of current for the lamps or motors upon it, so that no part of the current has to take the alternate and longer route through the connecting branches between the different circuits. Fig. 3 can be taken as representing one of the circuits of a well designed network.

On page 162 of Vol. XII. of the *Journal* of the Society of Telegraph Engineers and of Electricians, Messrs. Ayrton

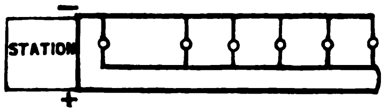

FIG. 1.

and Perry have shown that even in such a simple case as that when only two centres are being served, it is not possible to maintain both at a fixed standard pressure if the demand for current in each branch varies. With more than two centres the calculation becomes too complicated, and the results are obtained in a form too involved to be readily analysed; but it is clear that what is impossible in the case of two centres must be impossible in the case of three, four, or more centres. To prove this, we have only to consider that by singling out any two neighbouring centres, and allowing, for sake of argument, any amount of variation in all the other centres, we bring the case back to the simplest form, for which it has already been proved that, no matter how we may vary the pressure at the terminals of the line, it is impossible to keep the pressures at the two centres exactly at the standard value. By a similar reasoning we can prove this for any other pair in our line of centres, and thus it follows that the great ad-

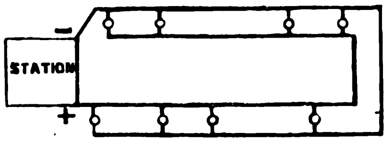

FIG. 2.

vantage claimed for this system of equalising the pressure all along the main line is purely imaginary.

Let c_1 and c_2 be the currents taken from the line of centres at A and B in Fig. 4., p_1 and p_2 the corresponding pressures (or differences of potential) in these points, E the difference at potential between the terminals P_1 and P_2 of the line, and ρ the resistance of a unit length of conductor, then by applications of Ohm's law we find

$$p_1 = E - (c_1 + c_2) D \rho + c_2 d \rho,$$
$$p_2 = E - (c_1 + c_2) D \rho + c_1 d \rho,$$

which equations are the same in substance as those given in the above mentioned journal.

If the two centres A and B were supplied at the same pressure, the difference between p_1 and p_2 must be zero, and this can only take place if

$$c_1 = c_2.$$

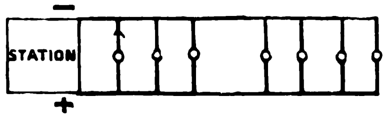

FIG. 3.

In all other cases we have

$$p_1 - p_2 = (c_2 - c_1) d \rho,$$

and therefore the difference between the pressures in A and B cannot remain constant if the currents vary. By varying the difference of potential between P_1 and P_2 (or between P_1 and $P_2{}^1$, which comes to the same thing), it is possible to keep the pressure at one of the two centres exactly at the proper standard, but then the pressure at the other centre must be wrong. It is impossible to make it right for both

Digitized by Google

at the same time, and as with a greater number of centres this difficulty is not removed, but probably somewhat increased, it follows that the line of centre system does not equalise the pressure.

It might be, however, objected that, by assuming only a few centres which necessarily are wide apart, we do not get a correct representation of the actual supply which will in most cases take place at a great number of points all more or less evenly distributed. Even in that case the pressure is not equalised. To put the most favourable conditions possible, we will assume that all along the line a constant quantity of current per unit length of main is taken. Let C be the total current used in the district, l the length of the line of centres, and x the distance of A from the station (Fig. 5), then the current passing by A in the positive lead is $C\left(\frac{l-x}{l}\right)$, that passing by A in the negative lead is $C\frac{x}{l}$.

Let p_1 be the absolute potential in the positive lead at the distance x from the station, and p_2 the absolute potential in the negative lead at the same distance; then, if we call the potentials at the distance $x + dx$ respectively $p_1 + dp_1$ and $p_2 + dp_2$, we find,

$$dp_1 = -C\left(\frac{l-x}{l}\right)\rho\, dx$$

$$dp_2 = -C\left(\frac{x}{l}\right)\rho\, dx,$$

ρ being now, as before, the resistance of a unit length of conductor.

By integration we find

$$p_1 = -C\rho x + \tfrac{1}{2}\frac{C\rho x^2}{l} + Q_1,$$

$$p_2 = -\tfrac{1}{2}\frac{C\rho x^2}{l} + Q_2.$$

Q_1 and Q_2 being constants which can be determined by noting that for $x = 0$ we have $p_1 = P_1$, and for $x = l$ we have $p_2 = P_2$,

$$p_1 = P_1 - \tfrac{1}{2}C\rho\left(\frac{2xl - x^2}{l}\right),$$

$$p_2 = P_2 + \tfrac{1}{2}C\rho\left(\frac{l^2 - x^2}{l}\right).$$

The difference of potential at the point A, or, as we have called it, the pressure in A, is, therefore,

$$p = p_1 - p_2,$$

$$p = P_1 - P_2 - \tfrac{1}{2}\frac{C\rho}{l}(2xl - 2x^2 + l^2).$$

We obtain the pressure at either terminal of the line by putting

$$x = 0 \text{ or } x = l,$$

$$p = P_1 - P_2 - \tfrac{1}{2}C\rho l.$$

If this be taken as a standard, the pressure at any distance x can be given with reference to it. It is

$$p = p_t - \frac{C\rho x}{l}(l - x).$$

By forming $\frac{dp}{dx} = 0$ we find that the point of greatest variation occurs for $x = \frac{1}{2}l$, that is, in the middle of the line. The pressure in this point is

$$p_m = p - \tfrac{1}{4}C\rho l,$$

and therefore the greatest possible variation in pressure is

$$\tfrac{1}{4}C\rho l.$$

It will be interesting to compare with this the greatest possible variation we would have to expect had we employed the same amount of copper in the network system. The arrangement in this case would be as in Fig. 6, where each of the branches carries half the current and is half the length as before.

In a former article (*see Electrician*, Vol. X., p. 81) it has been shown that the loss of pressure between the first and last parallel is equal to one-half of the electromotive force which would be necessary to drive the total current right round the the main leads if their far ends were joined up.

In this case the total current is $\frac{1}{2}$ C, the length of leads joined up is l, and hence the loss would be $\frac{1}{2}\cdot\frac{1}{2}C\rho l$. That is precisely the same as in the case of the line of centres arranged as in Fig. 5.

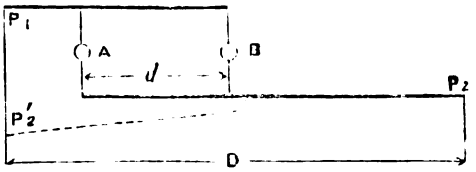

Fig. 4.

It will thus be seen that with regard to variation in pressure the double line of centres system offers no advantage whatever over the network system. It will be interesting to investigate whether the single line of centres system offers some such advantage. We must again assume that the same amount of copper is used, but now subdivided into three cables, instead of into four (Fig. 7). By virtue of this arrangement the resistance of the conductor per unit length is only $\frac{3}{4}$ of its former value, and the length of the line is one-half of what it was before. By making these corrections in the above formula for p, we find

$$p = P_1 - P_2 - \tfrac{3}{4}\frac{C\rho}{l}\left(xl - 2x^2 + \frac{l^2}{4}\right).$$

The greatest pressure occurs at the terminals where $x = 0$ and $x = \frac{1}{2}l$; it is

$$p_t = P_1 - P_2 - \tfrac{3}{4}\frac{C\rho l}{4}.$$

The least pressure will be found in the middle of the line; $x = \frac{1}{4}l$ gives

$$p_m = P_1 - P_2 - \tfrac{3}{4}\frac{3C\rho l}{8}.$$

Hence the greatest possible variation in pressure is

$$\tfrac{3}{4}\frac{C\rho l}{8}.$$

That is only $\frac{3}{8}$ of the variation we found in the double line of centres system.

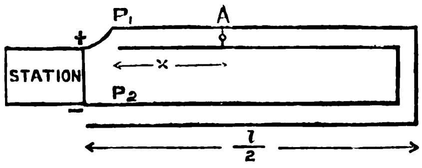

Fig. 5.

Next to equalising the pressure, the question as to the energy expended in heating the mains is of greatest interest. The current is sold to the customers at the pressure p, but it has to be put into the mains at the higher pressure E; hence, if we neglect leakage, $y = \frac{p}{E}$ is the efficiency of distribution.

If we compare the three systems with regard to the maximum loss of pressure, we find it for the network

$$E - p_m = \tfrac{1}{4}C\rho l,$$

for the double line of centres

$$E - p_m = \tfrac{3}{4}C\rho l,$$

and for the single line of centres

$$E - p_m = \tfrac{3}{4}\cdot\tfrac{7}{8}C\rho l.$$

That is to say, in the double line of centres system we waste three times, and in the single line of centres system we waste 2·63 times as much energy as in the network system. An example will be interesting. Assume we have to supply current on both sides of a street 500 yards long, the average demand for electricity being, say, one ampere per yard. In all we shall therefore have 1,000 amperes of current. To

Digitized by Google

carry this current safely we take a conductor whose resistance is $\rho = 0{\cdot}00004$ per yard (this is approximately the resistance of 19 strand ·205). We find $c \rho l = 40$, which, inserted into above formulæ, gives for the greatest variation of pressure along the line and for the horse-power lost in heating the mains the following figures:—

	Volts.	Horse-power.
Network system	10	13·4
Double lines of centre system	10	40·3
Single lines of centre system	3·75	35·3

They refer to the time when the full supply is on; at any other time the variation as well as the power wasted are less than given above. Now as to working our installation. It will be clear that in all the three systems some variation of pressure at the station in accordance with the varying demand for current would tend to let each individual customer have his supply at a more even pressure than in the case where absolutely no variation in the pressure at the station was made. For instance, in the case of the network, if the

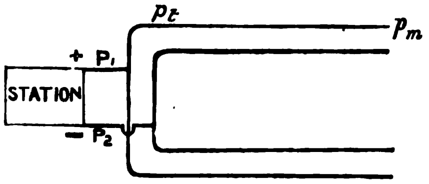

Fig. 6.

standard pressure were fixed at 150 volts, we would work up to 155 volts when sending out the maximum current of 1,000 amperes during certain hours of the evening; and during the daytime, if sending out only very little current, we would maintain only 150 volts. In this manner the customer nearest the station will receive the supply at 155 volts in the evening, and at 150 volts during the day, and the customer farthest from the station would receive 145 volts during the evening, and 150 volts during the day, whilst the pressure about the middle of the circuit would hardly vary at all. In providing the nearest customer with motors or lamps which require 152·5 volts, and the farthest customer with such requiring 147·5 volts, we should always be within $2\frac{1}{2}$ volts of our standard pressure; that is as near to it as can reasonably be demanded. In a similar manner we would arrange matters if either of the two other systems were adopted, only that in this case the variation at the stations would have to be far greater than five volts. As this is a most important point when deciding upon the merits of the different systems, a comparison of the figures in the following table will be use-

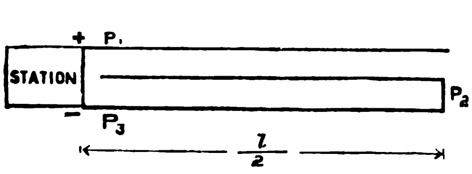

Fig. 7.

ful. N means network, D double, and S single line of centres system. The efficiency of distribution is taken as the ratio between the mean standard pressure of 150 volts and the maximum pressure required to be kept up at the station when the full supply is on:—

1,000 amperes, 500 yards, 150 volts.	N.	D.	S.
Minimum pressure at station ...	150	150	150
Maximum " " ...	155	175	170
Lowest standard of pressure ...	147·50	147·50	149·06
Highest " " ...	152·50	152·50	150·94
Greatest variation on the same premises	±2·50	±2·50	±0·94
Efficiency of distribution	96·8 %	85·8 %	88·2 %

This table is very instructive. In the first place it shows what an enormous price we have to pay for securing the imaginary advantage of even pressure in the double line of centres system. Twenty volts and 1,000 amperes is 26·6 horse-power absolutely wasted, without deriving the slightest benefit if compared with the network system. In the second place the table teaches us that, as regards evenness of pressure, the single line of centres system is certainly superior to the network system, but at a large cost of efficiency. We waste 20 horse-power in order to reduce the fluctuations of pressure by 1·56 volt, and it might well be asked whether so slight an advantage is worth this price.

There are, however, two strong practical reasons why, if possible, the line of centres system should be avoided. The one is that not only does it require that the pressure at the station should be varied between wide limits (in this case by 20 volts), but it also requires that at one and the same time there should be kept up at the station as many different pressures as there are lines of centres radiating from that station. It needs only a moment's consideration to show that this must considerably increase the amount of spare machinery, and introduce most objectionable complications into the service. The other and, if possible, still more important reason against the line of centres system is its inability of extension. It will readily be seen that two stations cannot possibly charge into the same line of centres, whilst with the network system this is quite feasible. Thus, any extension of the supply of electricity beyond the limits of the original area can easily be made if the mains form a complete network. New stations, charging into this common network, will have to be established, and by thus multiplying the generating points, any failure of one of these will not result in an interruption of supply in that part of the district, which would of necessity be the case were the district served on the line of centres system. Another advantage of the network system must not be lost sight of. It is this, that mains can be laid, tested, taken up, and repaired or replaced while the current is on.

ELEMENTARY ELECTRICITY.—IX.

(CONTINUED FROM P. 464, VOL. X.)

It has already been shown that the capacity of an isolated sphere is numerically equal to its radius. Henry Cavendish proved that the capacities of spheres are proportional to their linear dimensions, but having no definite unit of potential he had no reason for selecting the radius rather than the diameter of a sphere as the measure of its capacity, and, choosing the latter, he spoke of so many inches of electricity, by which he meant the quantity of electricity which would be imparted to a sphere of that number of inches in diameter when charged to a definite potential, as, for instance, that which could be obtained from his electric machine.

Having constructed a metal sphere about a foot (12·1in.) in diameter Cavendish proceeded to determine the capacities of other conductors by comparison with his sphere. In making these comparisons he employed a "trial plate" consisting of two pieces of tin plate which could be made to slide over one another, and thus the capacity of the trial plate could be varied. To compare the capacities of two bodies, A and B, he charged one of them, A, positively, and the trial plate negatively, but to the same numerical potential, and adjusted the capacity of the trial plate so that, on connecting it with the body A, the charges exactly neutralised each other. He then repeated the experiment with the body B, and compared the dimensions of the trial plate in the two cases. He determined (not quite accurately) the dimensions of a square equivalent in capacity to the trial plate, for different positions of the trial plate, and knowing that the capacities of similar figures are proportional to their linear dimensions (this he proved experimentally), he had all the data requisite for the comparisons of the capacities of A and B. With this apparatus Cavendish tested the capacities of plates of different materials and different thicknesses, and, making a rough correction for the thickness, found that the capacity was independent of the material. In

Digitized by Google

trying gold leaf, charcoal powder, gum arabic, tinfoil, &c., he spread the material on glass plates.

In comparing the capacities of bodies of different forms, Cavendish arrived at the following results:—

	Capacity.
A globe 12·1in. in diameter	1·000
A tin circle 18·5in. in diameter	·992

In comparing the capacities of coated panes, *i.e.*, of accumulators consisting of a plate of glass or other dielectric coated on each side by a conductor, Cavendish employed a trial plate, consisting of a sheet of glass, having its lower side entirely covered with tinfoil, but its upper surface only partially covered. Plates of brass were provided which could be made to slide over the tinfoil on the upper surface, and cover any desired portion of the plate. It was in dealing with this apparatus that Cavendish found difficulties arising from the creeping of the electricity from the edges of the metal over the surface of the glass, and was obliged to introduce a correction based on the assumption that for a particular kind of glass the creeping of the electricity produced the same effect as the enlargement of the armature by a definite amount in every direction. Cavendish concluded that with glass plates, ·2in. in thickness, the electricity spreads ·07in. all round the metal coating instantaneously, and that over this space the electricity has the same density as on the armature. This he determined by using different armatures having the same areas but some having much greater perimeters than others, and comparing their capacities. On rapidly charging and discharging such a coated pane, a beautiful luminous corona appears around the edge of the armature. This is well seen in the Leyden jars attached to the conductors of a Voss machine when the machine is giving spark discharge through three or four inches of air.

Cavendish provided himself with a set of ten coated panes, three having, according to computation, equal capacities, which we may denote by *c*; the next three had each a capacity of 3 *c*, the next three of $3^2 c$ or 9 *c*, and the last plate had a capacity of $3^3 c$, or 27 *c*, making altogether a capacity of 66 *c*. He first proved that the capacities of these plates were not sensibly affected by being placed near each other. This agrees with our explanation of the action of the Leyden jar. The slight disagreement between their computed and their actual capacities Cavendish explained by the spreading of the electricity above described.

By constructing small coated panes having the same capacities as the globe, of 12·1in. diameter, Cavendish determined the capacities of each of the coated panes in terms of that of the globe. In comparing his results with theory he took into account the fact that the proximity of the walls, ceiling, &c., of the room increased the capacity of the sphere, and he treated the room as itself a sphere 16ft. in diameter.

Employing two metal plates separated by little pillars of sealing wax, Cavendish measured the capacity of an air condenser.

The results of the measurements of the coated glass panes showed that their capacities were about eight times that which Cavendish's theory indicated, on the assumption that the electricity did not soak into the glass. By grinding down plates of glass so as to leave only the central portions Cavendish found that the outer layers were as good insulators as the inner layers; and the conclusion at which he arrived was that the glass consisted of portions, occupying in all about seven-eighths of its volume, which were comparatively good conductors, so that as far as action *across* the glass plate was concerned it behaved as though it consisted of alternate very thin layers of air and metal, the total thickness of the metal being about seven times that of the air. The result of Cavendish's measurements would be expressed in Faraday's language by saying that the specific inductive capacity of Cavendish's glass was about 8.

Cavendish afterwards observed that the charge of a glass condenser depends very much on the time during which it is charging, and that it "contained more electricity when it continued charged a good while than when charged and discharged immediately." This phenomenon of electric absorption occasions great discrepancies between measurements of specific inductive capacity, especially of glass, when the period of charging is in one case a second or two, and in the other very short, such as one ten-thousandth of a second, and it appears that a great deal of "absorption" takes place in a very small fraction of a second.

Cavendish determined the specific inductive capacities of substances other than glass, such as shellac, beeswax, and a mixture of beeswax and resin. Of these shellac had the greatest specific inductive capacity, but it was not much more than half that of glass.

After Cavendish the next worker in this subject was Faraday, who rediscovered specific inductive capacity, as previously stated. In 1871 Messrs. Gibson and Barclay published a paper on the specific inductive capacity of paraffin, a great impetus having been given to experimental work in this department by the publication of Clerk Maxwell's electromagnetic theory of light, for, according to this theory, the refractive index of a non-magnetic medium (and the magnetic permeability of nearly all transparent media is sensibly the same as that of air) ought to be equal to the square root of its specific inductive capacity, and this equality appears to afford the most ready means of testing the validity of the theory. Messrs. Gibson and Barclay's results, obtained with separate paraffin condensers, gave for the specific inductive capacity of paraffin the numbers 1·975 and 1·977 respectively.

Boltzmann employed a condenser, consisting of two metal plates, the distance between which could be varied, the plates moving so as to remain parallel to one another. Between these metal plates a thick plate of the dielectric to be tested could be introduced. The capacity of the condenser was compared with that of a pair of quadrants of the electrometer, which served to make the measurements, first, when there was only air between the plates of the condenser; and, secondly, when the plate of the dielectric was introduced. The comparison was made by noting the deflection of the electrometer when it was connected directly to the charging battery, and then, having discharged the electrometer, its deflection was noticed when the condenser was first charged from the battery, then insulated, and then connected with the electrometer. As these connections could be made and broken in rapid succession, there was not much time for absorption. If the deflection of the electrometer when connected with the battery was 100 and when connected with the condenser 90, it is clear that the charging of the quadrants of the electrometer reduced the potential of the condenser by 10 per cent., and the capacity of the condenser must, therefore, have been nine times that of the quadrants.

When a conductor is introduced into an electric field it suffers electric displacement, and one side of the body becomes positively charged and the other negatively charged. Such a conductor, with its induced surface electrification, will have a tendency to move towards that part of the electric field where the electric force is greatest.

If, instead of a conductor, a non-conducting body whose specific inductive capacity is greater than that of the electric field be employed, it will behave as though there were a surface electrification induced upon it similar to that upon the conductor, but less in amount, its amount increasing with the specific inductive capacity of its substance. Hence a non-conducting body placed in an electric field will, like a conductor, tend to move to the strongest part of the field, and will be attracted by any strongly electrified conductor, the amount of the attraction depending on the specific inductive capacity of the body.

As an example of the similarity in behaviour of a conductor and a dielectric of great specific inductive capacity we may consider the following:—Two plates, A and B, of an air condenser are placed an inch apart, A is charged positively and B connected to the earth. An insulated plate of metal half an inch thick is then introduced between the plates so as not to touch them. The side of this plate near to A will receive a negative charge and the other side an equal positive charge, while the potential of A will be

Digitized by Google

diminished, the capacity of the condenser being increased, as if the plates A and B had been brought up within half an inch of each other. The metal plate, in fact, is equivalent to a plate of air of no sensible thickness. A metal behaves as though it had an infinite specific inductive capacity.

Now, suppose the plate of metal replaced by a glass plate of the same thickness. The plate will behave as though the side near to A were electrified negatively, and that near to B electrified positively, but these apparent charges will be less than the actual surface electrification of the metal plate. The result is that the potential of A will be reduced, but not to the same extent as when the metal plate was employed, and the capacity of the condenser will be increased by an amount depending on the specific inductive capacity of the glass.

If a little glass ball be brought near to a positively charged conductor, it will behave as though it had a negative charge on the portion of its surface near the conductor, and an equal positive charge on the part which is more remote. Hence the sphere will be attracted by the charged conductor, the amount of attraction depending on its specific inductive capacity. Boltzmann compared the attractions exerted by a charged metal sphere upon an insulated and uncharged ball of metal, and upon an equal ball of resin, ebonite, sulphur, &c., and hence calculated the specific inductive capacity of the sulphur or other material. To diminish the errors due to absorption or imperfect insulation, the charge of the attracting sphere was reversed by means of a tuning fork 180 times in a second.

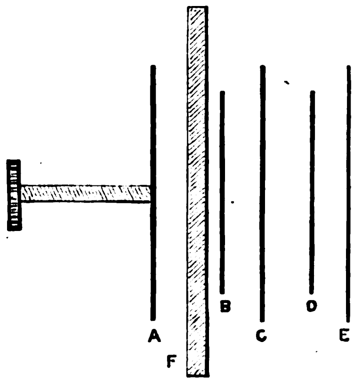
In experimenting with a sphere of crystalline sulphur Boltzmann found that its specific inductive capacities (like its refractive indices) were different for different directions in the crystal. The values of the specific inductive capacities when the electric stress acted along the principal axis of elasticity were 4·773, 3·970, and 3·811 respectively.

Dr. Hopkinson determined the specific inductive capacity, or electrostatic capacity, of different specimens of glass by means of a quadrant electrometer and the sliding condenser used by Gibson and Barclay. This sliding condenser took the place of Cavendish's trial plates. Its capacity could be varied at will by causing a cylindrical conductor to slide in or out of a cylindrical tube. The whole capacity of the sliding condenser could not be determined, but the increase or decrease in the capacity due to a measured displacement of the tube could be readily calculated. The glass whose specific inductive capacity was to be determined was placed between the plates of a very carefully constructed air condenser. The sliding condenser and the air condenser were charged, the one positively and the other negatively, but to (numerically) equal potentials by means of a battery. The battery having been removed, the condensers were connected together, and then both connected with an electrometer. The capacity of the sliding condenser was changed till, on repeating the experiment, the electrometer remained unaffected. When this was the case the capacity of the air condenser and the sliding condenser were equal. On introducing a plate of glass between the parallel plates of the air condenser its capacity was increased, but by means of a screw, the plate which was connected to earth was withdrawn from the receiving plate until the capacity of the condenser, with the glass plate inserted, was equal to that of the sliding condenser, and therefore to that which the air condenser originally possessed. By observing the distance through which the plate had to be moved, the thickness of the plate of air which was equal in its dielectric action to the plate of glass could be determined, and hence the specific inductive capacity of the glass was found. The specific inductive capacities of different specimens of optical glass varied from 6·57 for very light flint to 10·1 for double extra dense flint of specific gravity 4·5.

The principle of this and the method next to be described will be understood from the following:—

The capacity of an air condenser in which the distance between the plates is very small compared with their diameters, so that the excessive amount of electrification accumulated near the edges of the plates may be neglected, in comparison with the whole charge, is inversely proportional to the distance between the plates. Hence, if the distance be reduced to one-half, the capacity will be doubled, and so on. Suppose a plate of paraffin introduced between the plates of the condenser produces the same increase of capacity as would be produced by reducing the distance between the plates by half the thickness of the paraffin. Then it is clear that a plate of paraffin acts like a plate of air of half its thickness, and a condenser having paraffin for its dielectric would have double the capacity of a condenser otherwise equal, but having air for its dielectric. Hence the specific inductive capacity of paraffin must be 2. If, on inserting the paraffin plate, the distance between the condenser plates were increased by half the thickness of the paraffin plate, the capacity would be the same as before the introduction of the paraffin. If a glass plate is employed to keep the capacity unchanged, and the distance between the metal plates has to be increased by seven-eighths of the thickness of the glass, it follows that the glass plate is equivalent to a plate of air of one-eighth its thickness, and the specific inductive capacity of glass is 8.

The specific inductive capacities of several dielectrics were measured by Mr. J. E. H. Gordon by means of the electrostatic induction balance, and the results, together with an account of the experiments, were published in the *Phil. Trans.* for 1879. The balance consisted of fine metal plates, A, B, C, D, E, placed parallel to each other and at equal distances, except in the case of the plate A, which was movable. The plates B and D were connected to the quadrants of an electrometer, which served to determine if there were any difference of potential between them; C was connected with



the needle of the electrometer, and the Leyden jar to which the needle is generally connected was removed. The plates A and E were connected together. The plate C was connected with one pole of an induction coil, and A and B were connected with the other pole, while by means of a high speed brake the primary circuit was made and broken, so that the electrification of the plates A and E and of the plate C with the electrometer needle were reversed 12,000 times in a second. If everything in the balance were symmetrical, the plates B and D would be affected in exactly the same manner, and the needle of the electrometer would remain at rest; but if the induction of A upon B were greater than that of E upon D, the induction of C upon B and D being supposed to be the same, then, when A had a positive charge, the quadrants connected with B would have a higher potential than those connected with D, and the negatively electrified needle would turn towards the quadrants connected with B. But as soon as the electrification of A and E was reversed so as to be negative the quadrants connected with B would be at a lower potential than those connected with D. But the same action which reversed the electrification of A and E also reversed that of C, and with it the electrification of the needle, which, therefore, became positively electrified, and turned towards the quadrant connected with B as before. Thus the reversal of the electrification of the needle, a contrivance due to Clerk Maxwell, enabled the electrifications of all the plates to be reversed many thousands of times in a second, while the electrometer behaved in the same way as if the charges had remained unchanged.

ROCKS AHEAD.

No doubt the choice of title for the heading of a leading article is infinite, but when the title is new it is often inappropriate; hence we may be allowed to use one which has done good service before. In commencing our eleventh volume we feel that youth is merging into maturity, that with age our words gather force, the more so seeing that we have tried, in matters electrical, to be faithful guardians of public interests. We have heretofore cautioned the public when caution we felt was needed, and we have at other times attempted to inspire confidence when the outlook was particularly gloomy. In all our writings we have consistently endeavoured to avoid personalities, and to confine our remarks to questions of principle. It has been our misfortune to have to condemn certain electrical applications, but such condemnation was founded upon the knowledge that the laws of electricity and magnetism were in antagonism to those believed in by the sanguine inventor or promoter. The greatest difficulty a responsible scientific writer has to contend against is that of overcoming or combating the prejudices of inventors, and yet the majority of patented inventions are useless and valueless. A man should have faith in himself or his progress is stopped. The difficulty of conviction to a mistake is that most men—especially inventors—have an inherent tendency to believe in their own infallibility and in everybody else's fallibility. There exist at least two other classes of men who thoroughly believe in their own infallibility, and also that mankind as a rule may be reckoned as utterly stupid. These classes are promoters of public companies and those who pin their faith on pure speculation. The combination of patentees, promoters, and speculators forms a triumvirate whose concerted action has not only served to hamper the ship of electrical progress, but has managed to endanger its course by strewing "rocks ahead." If we take as a text the electric light companies which have sprung up like mushrooms by such concerted action during the last two or three years, what do we see? A time of excitement and reckless speculation, a time of depression and ruination, followed by the final act of passing through the court. Commercial enterprise is for a longer or shorter period brought almost to a standstill; real investors lose all confidence in such securities; capital is diverted elsewhere; progress is thus retarded, and the innocent suffer. There is absolutely no means of successfully fighting this concerted action while the daily press lends itself ignorantly or otherwise to pre-arranged plans, and we have, therefore, to witness periodically a recurrence of speculative excitement. Such a period we passed through last year, and now witness the depression, to be followed by the final act. Interested parties are doing all they can to stave off the evil day, but the result is inevitable. We had before us the balance-sheet of one of these concerns but recently, and were utterly amazed to find the company showing a profit and declaring a dividend, when a large portion of its assets consisted of shares in branch companies. The quotations of these shares are slightly higher—we suppose because of the dividend—but if we contemplate the future, and ask to know what work such companies are likely to do, the answer will not be very satisfactory. Before electric light work enters upon a safe footing these bubble companies must go—their promoters never meant real work—they intended to reap a harvest from the confiding public, and have done so to an enormous extent. As soon, however, as the public began to realise the position, their contributions ceased, and the operators, unable or unwilling to prey one upon another, saw the inflated quotations gradually shrinking towards the normal value of the shares, viz., nothing.

Let us consider another phase of electrical work, that of telephony. There is nothing more certain, and we have said this again and again, than that the Telegraph Department must sooner or later appropriate the telephonic system. Promoters of telephonic communication know this, and think, therefore, that excessive watering, and the extension of interests, means simply an increase in the amount to be ultimately paid by the taxpayer. Telephony is in its infancy, yet it seems pretty certain that all local transactions will be carried on by its aid, and that the Telegraph Department will loose a considerable portion of its income by the loss of the local messages. This loss may perhaps be replaced by the royalty paid by the companies, and at first sight the result of the extension of telephony might seem to be the anomalous one of the Government receiving a large amount in subsidies and doing no work. A little consideration will show that the value of telephony depends largely upon the numbers connected by the system. A merchant will not have two rival instruments in his place, and, further, the public will not tolerate the infinite increase of overhead wires. The larger American towns are already abolishing overhead wires, as we had practically done with regard to telegraphic wires, and must do with regard to telephonic wires as well. Then we have attempts to float companies to establish long distance

telephony. We will not say that ordinary telephonic communication over a thousand miles in America or Australia is impossible, but we will say, and that most emphatically, that at present it is not commercially possible. According to the *Electrical World* of New York the statements of the trials between that city and Chicago, as recently put forward to induce the public to support a new system, have been, to say the least, somewhat garbled. Even supposing them to have been correct, we would respectfully ask what allowance has been made for differences of climatic conditions in England and America by those who talk so glibly about long distance telephony? Progress in telephony is certain, but again the concerted action means "rocks ahead." In many cases the promoters of new companies introduce indefinite statements into their prospectuses in order to bring about a state of unrest in the minds of shareholders in existing companies. We have before us indication of such a state of unrest in the shape of a letter from a gentleman greatly interested in cable companies, who asks whether it is possible that promises recently made as regards telephony can be carried out, and whether telephony is likely to be used in cable work. It is from communications of this character that we are able to trace on every hand the injurious result of the work of the triumvirate. In this case we may say that there is no indication at present of telephony being successfully applied to cable work, and the shareholders of the cable companies may rest content even if telephony could be so applied to-morrow. They have the cables, and telephony *versus* telegraphy most probably means to them a simple change of instruments at the various stations. Instead of fearing the progress of telephony, those interested in cables should carefully watch it, support it, and if ultimately they can use it their expenses will be lessened. For the present, as we have said, the contest is between land telegraphs and telephony. The Government has promised a reduction of rates, which means increased lines, more instruments, and a larger staff, and this in the face of a competition that will grow keener every day. Who can foretell the end?

CORRESPONDENCE.

ELECTRICAL MACHINES AND THE TRANSMISSION OF POWER.

(TRANSLATION.)

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have only just received the last number of your paper, containing a letter from Mr. Gisbert Kapp, which compels me to ask you to accord me the right of reply in the columns of your next issue. If Mr. Gisbert Kapp considers the letter which you published from me as a joke, he would, perhaps, have done better in letting it pass unnoticed, whilst if he wished to provoke a discussion it would certainly have been worth his while to reply in a courteous manner to the communication which you deemed worthy of notice. Instead of doing this, Mr. G. Kapp stoops to personalities, always out of place in a discussion, and furnishes your readers with a fantastic interpretation of the idea put forward in my letter. It might, indeed, be asked why Mr. Kapp has so little to say on the subject matter of the question raised, and contents himself with demolishing the person of the correspondent who is so unlucky as to be possessed of ideas which do not agree with those of Mr. Kapp, and do not fall in with his long experience.

But to the facts:—

I have said that the general arrangement of the machines at the experiments carried out on the 4th March at the workshops of the Northern Railway, Paris, differed essentially from the conditions necessary to the transmission of power on account of the direct connection between the two machines. I added that M. Hospitalier was struck with a happy thought in drawing the attention of those interested in M. Deprez's experiments to the influence of the derivations of current on the line. I shall permit myself to add to-day, although it will perhaps displease Mr. Kapp, that I think that the results announced since the 4th of March would have been entirely different if the machines had been otherwise connected, and if, in accordance with a desire expressed by one of the committee, an earth connection capable of being connected at will to the wire joining the two machines had been provided. Such is the sense of my comments on M. Deprez's experiments.

I will now pass to the combination I had thought to be able to offer as furnishing, perhaps, a more complete solution of a question which remains, on the whole, an open one. This part of my letter was purely interrogative. I will, therefore, make honourable amends for my ignorance as to the good conditions of working of machines; but I cannot admit that Mr. Kapp destroys the sense of my proposition by disproving the principle on which the fundamental idea was based.

I simply asked if, in the presence of the not very conclusive experiments we know of, it would not be opportune to seek, conjointly with the labours of M. Deprez, the solution of the problem of electrical transmission in "a system composed of two machines differing in type and dimensions; the generator without a core in its armature, and the receiver without wire in the magnetic field, that could be subject to induction [*fil de l'induit*]. (The translator made me say receiver without wire.) The receiving machine should have large dimensions as compared with the generator."

Mr. Kapp indulges in some mild pleasantry on reading the announcement of this combination. I shall therefore try to justify it, so far as it can be justified. The theory set up by M. Deprez led him to construct machines capable of working with relatively small currents, whilst they produced considerable electromotive forces. Now, to obtain a high electromotive force in a dynamo-electric machine without exceeding the speed accepted in practice, it is necessary to increase the length of the induced and inducing wire [*fil induit et du fil inducteur*]. We thus find ourselves between two equally great difficulties: Whether it is best to multiply the turns of wire without changing the size [of the machine], and have machines with fine wire, the resistance of which rapidly increases, which we are trying to avoid; or whether it is best to attempt to diminish the electrical resistance by increasing the diameter of the wire, which will increase the size of the machine to preposterous proportions. Mr. Cabanellas has proved that the influence of speed on eletrical resistance is to be found in machines in the shape of a deficit; but that this deficit of work, of electrical origin, was, so to speak, inappreciable with thick wire machines.

I was thus led to believe that it would be advantageous to make armatures without cores, since one could thus dispose of all the space occupied by this core, which would permit of the winding on of a greater length of thick wire, without changing the size of the machine. Further, by suppressing the core we at the same time get rid of the parasitic actions due to the production of Foucault currents. Thus, if there be no difficulty in constructing machines without cores, we have arrived at this fact; every advantage would accrue from designing these machines as generators for transmitting purposes.

As to the receiver, Mr. Kapp ought to have understood that the expression of which I thought to avail myself in a letter having no scientific pretension could only be attributed to a kind of movable electro-magnet, resembling in its construction the Siemens or Griscom coil. All the electric catechism of which he makes display is, therefore, on this occasion, of no avail (the expression was, perhaps, incomplete, and badly rendered in the translation), since all that I wished to point out may evidently be summed up in this:—Increase the number of turns of wire in the generator at the expense of the size of the core, so as to obtain a greater inductive action and no detrimental parasitic action (Foucault currents),

Digitized by Google

and do the opposite in the receiver by favouring the production of magnetic reaction at the expense of direct induction. By this means, as there is no wire in the field, there will be a corresponding reduction in the counter effects. The receiver would not be an induction motor, but a machine (actuated) by successive magnetisations, and by increasing the dimensions of the magnets we can increase the capacity for magnetisation. Moreover, by reducing the distance between the movable armature and the fixed electro-magnets to a minimum, we obtain the maximum effect from the magnetic forces—we utilise them completely.

I think that a movable armature for the receiver, resembling the types I have just indicated, and revolving between suitable electro-magnets, would have a *raison d'être* of its own for power transmitting purposes, since it is known that Griscom's electromotor is benefited by the induced currents which are developed in it. From this to the hope of being able, not to annihilate the counter electromotive force, as Mr. Kapp makes me say, but to regulate [*orienter*] it, in such a manner that its action may not be immediately opposed to the force generated, is but a step. I have made this step and asked myself whether it may not be possible to reduce this loss of power, which is due to the fact that the second machine produces by induction a current which opposes that from the motor; or, whether it is necessary to seek refuge from the dilemma by looking for the increase of the relative work in the decrease of the absolute work, and *vice versâ*? Does Mr. Kapp see any reason why a zealous, though young and innocent disciple of electrical science should not be possessed with such an idea?

We all know that it is impossible to deny the part played by inverse electromotive force. Deprez has illustrated it by a beautiful experiment. We also know that this counter-electromotive force is one of the elements which determines the power developed by the motor; that in this sense it forms an attribute of one of the factors of mechanical work. But precisely because effort takes places, and a path is traversed in doing this work, there would, perhaps, be opportunity for causing the armature to revolve less quickly for a similar path, and for diminishing its inductive reaction by a device which I cannot make known now, and which I can only foreshadow to those who are familiar with the construction of machines. I do not pretend, however, that the solution is easy, nor, indeed, a practical possibility. It is merely a question of finding out whether something cannot be attempted with the view of decreasing the loss due to the production of inverse force, and whether we must always be content with a useful return of from thirty to forty per cent., although the two machines may only be separated by a few metres. Can Mr. Kapp throw light on this question? If he can, I shall yet think myself happy in having been for a space the object of his sarcasm.

I now come to the latter portion of his letter and of mine. I said that the phenomenon which occurs in an electrical system of two machines connected by a conductor is the same as that which we should *observe* in a system with two ventilating fans, acting by centrifugal force, one of which might be [supposed to be] set in motion by means of the air supplied by the other, and both of which might [be supposed to] discharge into [*déboucheraient*] the same pipe. In making use of this conditional style of phraseology, I sufficiently implied that no such system was in existence; Mr. Kapp's insistance on the absurdity of such a mode of transmission has, therefore, no *raison d'être*, and I am surprised that this shadowy sketch of what might be could have led him into error. As to the analogy between the two systems, electric and pneumatic, which my opponent does not recognise, I will demonstrate it, if Mr. Kapp will be good enough to give his address—the letter necessary to do this would be too long and uninteresting for insertion in the columns of your esteemed paper.

I will also show Mr. Kapp, if he wishes, how, in a compound acting fan [*ventilateur à recouvrement*], when one sector passes before the escapement, this sector possesses a dynamical tension, and how this by detent becomes statical. He will then see how it is possible to inflect the indraught current which is generated by the second fan in such a way that it no longer directly neutralises the motion communicated by the first apparatus.

I venture to hope that I shall have succeeded in removing the difficulty so forcibly expressed by Mr. Kapp in his letter, and that he may, perhaps, be less inclined to laugh at efforts such as every one is at liberty to make with a view to solving a question of capital importance.

If, however, Mr. Kapp desires to continue the discussion, he must do so in a courteous manner. I have accepted the lesson he gave me with sufficient grace; it remains for him to make good use of the advice I give.

As one of your most constant readers, I reckon on your kindness for the insertion of this letter as soon as possible.—Yours, &c. A. BANDSEPT, N.F.

Chaussée de Wavre, 15, Bruxelles,
2nd May, 1883.

THE LIGHTING OF NOTTINGHAM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I believe that your number of May 12 will be found so valuable to electric light engineers as a reference, on account of the three excellent letters of "M. N.," "Henry Lea," and "Edw. H. Winfield," that I trust you will reprint these letters, and attach them to one of the very useful supplements you are from time to time issuing.

I should like to call the attention of your inventive readers to the fifth paragraph of "M. N.'s" letter regarding condensing water, and the train of ideas suggested thereby. It is abundantly clear that if the distribution of electric light and power is to be carried out with currents not exceeding 200 volts E.M.F. (the limits at present fixed by the Board of Trade), every large town will have in its midst a large number of generating centres, at each of which two or three thousand horse-power must be generated by means of steam engines and their boilers.

Now, I have little fear that the persevering genius of modern mechanical engineers will overcome in most cases the difficulties of getting the engines, fuel, feed-water, and, in some cases, condensing water, into the very limited space available as sites for these stations.

But I now ask you—Is there no royal road out of our difficulties? What can the makers of gas engines do for us? Hitherto the gas-engine builders have confined their efforts to comparatively small engines (I believe about sixty horse-power actually given off at the fly-wheel is the largest result yet obtained by Messrs. Crossley Bros.).

Supposing that a gas engine giving off 500 horse-power were available, and could be put down at a cost not exceeding that for a steam engine and boiler of equal size, is it probable that it could be worked at a cost for gas, oil, and attendance of 4d. per horse-power per hour in a town where gas is 2s. per 1,000 cubic feet?

If this question can be answered in the affirmative, it will greatly affect the future of electric light and power distribution, it will convert the gas companies from their position as our rivals to that of our best friends. The gas and the electric undertaking could thus be easily wedded together.

The difficult questions of boiler space, smoke and steam nuisance, transport of fuel, &c., would be avoided, and the desiderata of electric light and power, with gas heating and cooking, introduced into every dwelling house, workshop, and manufactory would be attained.

The gas engine we require for this purpose must be a high speed engine, capable of running direct, coupled to the dynamo, at fully 300 revolutions per minute. It must be perfectly balanced, and there must be no audible or sensible shock from the explosions in the cylinders.

If I am successful in calling the attention of an enlarged circle of thinkers to this interesting problem, my object in writing to you, Sir, will be attained.—Yours, &c.,

London, 17th May. R. E. CROMPTON.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There is one point in connection with this tender

Digitized by Google

which does not appear to have been touched on by any of the critics, although it seems to me to involve an obvious underestimate of the cost of production. I refer to the power stated to be required for each dynamo when running its maximum number of lamps—1,530 indicated horse-power for 15,000 lamps—or say in round numbers one indicated horse-power for each 10 lamps of 20 candles = 200 candles per indicated horse-power. Taking a 50 volt Swan lamp as using 1·4 ampere of current, this gives us 70 watts as the power required for each lamp. If we assume the 70 volt lamps proposed to be employed in the Nottingham installation to take the same power, this gives us $\frac{746}{70} = 10{\cdot}65$ lamps as the theoretical possible per horse-power. Presuming an efficiency of 90 per cent. for the dynamo, 90 per cent. for the lamp, and a loss of current equal to $7\frac{1}{2}$ per cent. on the mains, we get, not 10 lamps as indicated by the specification, but as nearly as may be 8 lamps per effective horse-power, which makes an addition of nearly £2,000 per annum to the coal account.

The proposal to lead two sets of poles to each house is but shirking one of the essential conditions of central station lighting—I mean running the dynamos in multiple arc. The contractors apparently have not thought themselves equal to the task of doing what has been done for months past in New York by Edison at the Pearl-street installation.—Yours, &c., CONTINUOUS CURRENT.

[With reference to the 2,500 hours mentioned in the specification, and criticised by our correspondents last week, we may say that we have been informed that the mills in Nottingham run pretty continuously night and day, and hence the lamp-hours per year would be in excess of those in ordinary towns. We supposed that careful inquiries had been made in Nottingham in order to obtain correct these figures in the specification.—ED. *E.*]

TELEPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We notice in your last issue a communication from Mr. Munro, in which he goes considerably out of his way in order to mention our metal microphone in a manner which we must object to as not in accordance with fact.

The metal transmitter patented by us is *not* "a simple hammer and anvil microphone of the kind employed before by Professor Hughes." It might with equal justice be stated that "Professor Hughes's hammer and anvil microphone is a simple contact matter employed before by Philip Reis, the only difference being that one uses platinum, the other carbon."

The experiments of Professor Hughes, when published some five years ago, did not enable any one to construct a perfect transmitter. The effects obtained from the pencil, hammer and anvil, and other microphones, were certainly very startling at first, but it was soon found that to hear the tramp of a fly or the tick of a watch was one thing, while to hear distinct articulation of speech was another. Hundreds of experimenters have tried, and are still trying, to improve the microphone, and we can say from our own experience that it is possible to spend years in the pursuit of this object. If an improvement be ever so insignificant looking, but produces results which the original form was incapable of achieving, the improver has a right to call the improvement by his name. Thus we considered our carbon transmitter to be an improvement upon Professor Hughes's microphone, and we now hold our metal transmitter to be an improvement upon Reis's instrument.

Mr. Munro fears that metal microphones of this kind are not quite practical owing to the adhesion and wasting of the points. We are happy to be able to allay Mr. Munro's fears by the assurance that we easily and surely prevent the adhesion of the contacts in our metal transmitter, and that no wasting of the points can take place, simply because there are no points.

We may mention that one of our transmitters has now been in constant use for the last 14 months without requiring any attention or adjustment.—Yours, &c.,

R. and M. THEILER.

ELECTRIC LIGHTING IN VIENNA.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the *Daily News* of the 12th inst. a telegram appeared from their special correspondent at Vienna stating that "the day previous the electric light was tried in the Opera House there with complete success. 200 accumulators fed 1,236 lamps distributed all over the theatre."

Since then I have had many communications pointing out that this telegram showed the existence of a successful rival accumulator.

May I, therefore, beg you to be kind enough to announce that the complete success arrived at in the Opera House in Vienna was achieved by Faure-Sellon-Volckmar accumulators constructed in that city by Mr. Lewis Volckmar, one of our electrical engineers, under the auspices of the Anglo-Austrian Brush Electrical Company (Limited).—Yours, &c.,

T. M. COLLET, General Manager.

Electrical Power Storage Company (Limited),

THE BRUSH SYSTEM IN ABERDEEN.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The remark you make in *The Electrician* of the 5th inst., that the electric light in Aberdeen cost six and a-half times as much as gas, will lead to the erroneous conclusion being formed that the supply of electricity on a large scale will be proportionally costly.

The labour charged, for instance, for a small installation such as the one the Brush Company of Scotland erected in Aberdeen is nearly as great as that required to run one of their large dynamos with 40 lights in circuit, and this number of lamps might be increased to 80 or 120 with a still lessened cost per lamp. But, besides this diminution of expense with a large supply, the cost of the Aberdeen street lighting was increased in an exceptional manner by the employment of labour not usual in a 16-light installation. Thus, owing to the boiler being in an adjoining house, the services of an additional man were necessary to stoke, while other expenses were, I believe, incurred in keeping the motor, which was an old type beam engine, in good repair. Every exertion was made by the city gas engineer, who had the motive power under his charge, to render the engine as efficient as it could be made for the unusual work it had to perform.

It does not appear to me extraordinary, therefore, that the expenses should have run up, but I would draw attention to the fact that an installation of this kind, even on the Brush system, which is more economical than others, affords no criterion of the cost under other conditions. For instance, in factories and workshops where steam power is available the engineer, stoker, and special dynamo attendant are not required, and the great part of the maintenance expenses are thus saved. Again, the cost of electricity in a town supply of, say, 50,000 incandescent lights and arc lamps, where all charges will be reduced to a system, with the employment of large dynamos, engines, and labour-saving appliances, cannot be estimated by a trial of this kind.

The use of such an installation is rather to give the people an opportunity of judging the advantages of the electric light, and with this purpose in view the Brush Company of Scotland are now exhibiting in Aberdeen the incandescent system of electric lighting, both direct from the dynamos and by accumulators.—Yours, &c.,

E. W. BECKINGSALE.

Glasgow, May 14.

[We would point out that the statement that the electric light in Aberdeen cost "six and a-half times more" than gas was made by the Gas and Lighting Committee of the

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Will you allow me to say a few words on this subject with reference to Dr. Paget Higgs's letter in your impression of the 14th ult.

I venture to think that the results obtained by Dr. Higgs in the experiments he describes do not tend to prove anything either for or against a "screening" action of the core of the Gramme ring.

It is an elementary fact in connection with electro-magnetism that, (1) If a coil of wire is placed in a magnetic field, and a current is produced in the wire by any convenient means, lines of force will either be thrust out of, or concentrated into, the field of the coil, according as the direction of the current is such as to create lines of force of opposite or like direction to those existing in the neighbourhood; and (2) When a current is induced in a coil by the addition of lines of force to its field, the direction of that current is such as to create lines of force of opposite direction to those which produced it.

Now, it is evident from these facts that, if we take a Gramme ring with *no* iron in its core and rotate it in a magnetic field, although when there is no current flowing through it the bulk of the lines of force produced by the field magnets may pass through it, in a sense which would tend to produce an E.M.F., yet a slight current in the coil may be sufficient to thrust them on one side, and practically divide the field of force into two, the greater part of the lines of force lying between the edges of the pole pieces (supposing these to be of the usual form).

In the sketch Fig. 1 is intended to represent the normal condition of the field when no current is flowing through the ring, Fig. 2 the condition when a current is flowing.

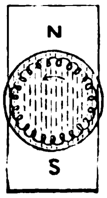

Fig. 1.

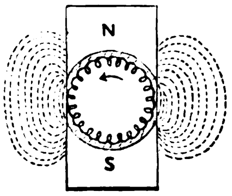

Fig. 2.

If the distances through which the lines of force must pass in order to join the pole pieces in the two cases are compared, it will be seen that they do not differ very materially; consequently a very small force will decide their position.

The presence of a complete iron ring between the pole pieces will have the effect of shortening the distance from one pole piece to the other enormously, and if the ring be large enough to touch the two poles, the external field will be almost inappreciable, the bulk of lines of force passing through the iron ring between the poles. If the ring do not actually touch, the distance separating it from the pole pieces will determine its effectiveness in reducing the external field, or, what is of utmost importance, its effectiveness in concentrating the lines of force into itself. The effect of cutting the core into segments in the manner described by Dr. Higgs is certainly equivalent to increasing the distance by the *sum* of half the distances between the iron segments—probably very much more; and thus we may explain the loss of E.M.F. by considering that the isolated (magnetically) segments of iron are unable to effectively oppose the dispersing action of the current on the magnetic field.

Applying the pole of a magnet in the manner described by Dr. Higgs would naturally have the effect of forcing more of the lines of force into the field of the revolving armature, and consequently increasing the E.M.F.

As regards the question as to whether the inner or outer wire of the ring is most efficacious, I quite agree with those of Mr. Mordey's opinion, *i.e.*, that the E.M.F. is created in the outer halves of each turn; but then it seems to me that if the core is magnetised to saturation by the inductive action of the pole pieces, the E.M.F. created in any one turn for a given speed is at a maximum, *although it is all created in half the wire.*

If we conceive a long soft iron bar, of the same section as the core of the ring, to be magnetised to saturation in such a manner that the poles are the same distance apart as those induced in a Gramme ring, and suppose it to pass through a coil of the same number of turns as the coils on the ring, and to be commutated in the same manner, it seems to me that the E.M.F. created in the coil will be quite independent of the course of the magnetism in the bar, *unless the outer coils can be made to cut more lines of force than those which pass into the bar.* I do not think it is impossible to effect this, but that the number cut in excess of those which pass into the core in the Gramme and kindred machines, as generally constructed, is inconsiderable I think there can be no doubt.

I shall be glad to know the opinion of some of your talented correspondents on this view of the action of the core of the Gramme ring.—Yours, &c., W. B. Sayers.

April 9, 1883.

ON A SIMPLE FORMULA FOR DETERMINING THE INSULATION OF A SECTION OF WIRE, MEASURED THROUGH AN INTERMEDIATE LEAD.*

BY G. A. HAMILTON.

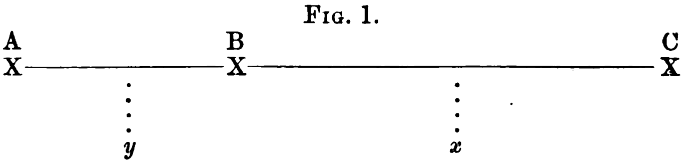
It frequently happens that when the insulation resistance of a section of line or an underground wire or cable is wanted, various impediments prevent reliable measurements from being made at either terminal of the same.

At a cable house it may be the wind or the jar resulting from passing trains along a railroad, the bumping of a ferry boat against the dock, or the inductive disturbance due to the motion of its machinery; or, again, it may be the constant passing of trains along the elevated road that interferes. In some of the cases enumerated it is undoubtedly possible to obtain correct measurements if time is a matter of no consequence, but when it is an important factor the delays and incident annoyances make the measurement of 10, 20, or more conductors anything but a pleasant occupation.

Having experienced all these troubles in and around New York, the writer has made it a practice, in all cases where approximate accuracy is desired, to adopt the old plan of measuring the insulation through a lead of such length as convenience or the circumstances of the case will permit, and at the same time, allow of placing the galvanometer where its indications may be depended upon. The resistance sought is then deduced from the combined results obtained.

As he does not remember of having seen the formula he used outside of his own memoranda, and thinking it may prove interesting to some of the members, he is induced to give its full development herewith:—

Fig. 1.



Let A B (Fig. 1), represent the lead and B C the conductor whose insulation resistance is sought, the conductor resistance in each case being a *small fraction* of the insulation resistance, which latter may be represented by y and x respectively.

Under these circumstances, with A B and B C joined and the end at C insulated, measurements made at A will give the joint insulation of the two conductors, which we will designate by z.

* Paper read before the New York Electrical Society, April 6. Reprinted from the *Operator*.

Digitized by Google

Then $z = \dfrac{x\,y}{x + y}$ and the insulation sought will consequently be

$$x = \frac{y\,z}{y - z} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

As x y and z are usually high, measurements by the bridge method are not often practicable, and a mirror or other galvanometer, whose deflections are proportional to the current circulating in its coils, is then generally employed. When this is the case the constant of the instrument must be known. This is obtained in the well-known manner by ascertaining what deflection it gives through a known resistance with a given battery. The resistance sought is then found by placing the same instrument and battery in circuit with it, noting the corresponding deflection and dividing the constant previously obtained by the latter deflection. The quotient is the resistance sought in ohms or megohms, as the case may be.

In using this method for determining the insulation of a section of line through a lead many persons would naturally take the round-about way of finding the resistance of the lead and joint resistance of lead and section tested, separately, and then combine the results as in formula 1. If, however, the combination is first effected, the resulting formula gives the required insulation with very little calculation. This is the plan the writer finds most convenient to practice:—

Let A represent the constant of the instrument, *i.e.*, the resistance through which, with a given battery, it will give one degree deflection;

d, the deflection obtained when the lead, instrument, and battery are in circuit;

D, the deflection when the lead, instrument, battery, and section whose insulation is wanted are in circuit.

The insulation of the lead would then be

$y = \dfrac{A}{d}$ or, if reverse currents are used, as is proper,

$$y = \frac{A}{\dfrac{\Sigma \pm d'}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where Σ is a symbol only, and indicates that the sum of the + and − deflections are to be taken.

The joint insulation of lead and section would, in like manner, be

$$z = \frac{A}{\dfrac{\Sigma \pm D'}{2}} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Substituting these values in equation (1), we have

$$x = \frac{\dfrac{A}{\frac{\Sigma \pm d'}{2}} \times \dfrac{A}{\frac{\Sigma \pm D'}{2}}}{\dfrac{A}{\frac{\Sigma \pm d'}{2}} - \dfrac{A}{\frac{\Sigma \pm D'}{2}}} = \frac{\dfrac{4A^2}{\Sigma(\pm d' \times \pm D)'}}{\dfrac{2A}{\Sigma \pm d'} - \dfrac{2A}{\Sigma \pm D'}} \quad . \quad . \quad (4)$$

Dividing by 2A, and multiplying — (both numerator and denominator) by $\Sigma\,(\pm\, d \times \pm\, D)$, the resulting equation takes the form

$$x = \frac{\dfrac{2\,A\,\Sigma\,(\pm\, d' \times \pm\, D')}{\Sigma\,(\pm\, d \times \pm\, D)}}{\Sigma\left\{\left(\dfrac{\pm\, d, \times \pm\, D'}{\pm\, d'}\right) - \left(\dfrac{\pm\, d' \times \pm\, D}{\pm\, D'}\right)\right\}}$$

which on cancellation of common factors becomes

$$x = \frac{2\,A}{\Sigma(\pm\, D' - \pm\, d,} \quad . \quad . \quad . \quad . \quad (5)$$

the most convenient form for use.

In the foregoing illustration a single + and − reading only are taken; if more are used the same should properly appear in the formula, and it is, of course, necessary that a like number of readings should be taken for the lead (whether they do or do not vary) as is taken in the joint measurements.

It will also be understood that when shunts are used they should be accounted for in the formula, as, for instance,

$$x = \frac{2\,A}{\Sigma \pm (D' \times \text{shunt} - \pm\, d' \times \text{shunt})}$$

This is supposed to have been done for A at first.

PRACTICAL TELEPHONY.

[We herewith commence a series of articles upon a subject which, so far as we know, has not yet been touched upon in any electrical publication, viz., practical telephony. These articles are contributed by one who has had a large experience, and, while there is no pretence to literary style, it is hoped that the subject is treated clearly, simply, and exhaustively. —Ed. *E.*]

The Leading-in Wires.—For this purpose No. 18 B.W.G. copper wire, covered with two coatings of gutta percha to a total thickness of No. 7 B.W.G. wound with strong tape, and, lastly, well covered with Stockholm tar, should be used. These wires should be retarred at frequent intervals to keep them in good condition. Paint is injurious to gutta percha. Messrs. Henley and Co. have lately introduced the ozokerit core, which has a slight advantage as regards price, whilst its durability is guaranteed to exceed that of gutta percha. Subjoined is a test of this core by the electrician of the General Post Office, W. H. Preece, Esq., F.R.S.:—

Conductor resistance	23·723 ohms.
Capacity	·281 micro-farad.
Insulation	8,196 megohms.
Temperature	75° Fah.

Tests of gutta percha core of similar length:—

Conductor resistance	22·36 ohms.
Capacity	·273 micro-farad.
Insulation	860 megohms.
Temperature	75° Fah.

It will be seen by this that its insulation is very high, and if it prove to be more durable for telephone leads than gutta percha (which at best is comparatively short-lived when exposed to the air), it should come into general use. It is made by forcing melted ozokerit paraffin into ordinary rubber core under heavy pressure. It would be more economical in the end if the leading-in wires were double-taped; they would then be better able to withstand the rough usage to which they are often subjected from the line men's feet when going up and down the poles, &c. Care should also be taken that a spare piece of gutta percha is wound round them where they touch corners of chimneys, walls, &c. The lead should make a short dip below, and then rise to the hole, where it enters the wall or window-frame, so that rain may run down and drip off at the bend instead of running into the building.

Where possible connect the main gutta percha lead direct to the instrument, it being much less liable to damage. In some cases this may be inadmissible from its unsightliness, when the lead must be joined to the ordinary paraffined wire, and the joint soldered with composite candle or resin. *Never use spirits.* When soldered the joint should be wrapped with tarred or india rubber tape, to prevent contact with other wires.

It may be as well to give instructions here how to solder a joint properly, a very easy operation in itself, although neglected by many fitters. The following articles must be provided:—A small spirit lamp; a small copper bit made from about 2in. of No. 8 copper wire, drawn to a blunt point at one end, with a steel wire screwed into the other, and this wire driven into a brad-awl handle. A small tin box to hold a short piece of composite candle or powdered resin; and, lastly, a small quantity of the best blowpipe solder. The iron, when new, and at intervals afterwards, will require tinning, which is done thus:—Make the iron bright with emery paper, heat it in the spirit lamp, and rub it on a piece of tin with a small piece of solder and composite or resin. This should give it a bright tinned surface. Now, to solder a joint. Scrape the wires bright, twist them firmly together, rub well over with composite, or dust the joint with powdered resin, heat the bit in the lamp, wipe the point with a piece of rag, touch it on the solder so that a small piece adheres, and apply it to the joint, rubbing it along. If this is properly done, a strong, clean joint is the result. This small copper bit

Digitized by Google

is sufficient for the small wires used indoors for telephonic purposes.

Terminal Board for Switch Room.—Figures 1, 2, 3, show a convenient terminal board for the leading-in wires. The main board is 6 feet by 3 feet, the terminals are double headed and 3 inches apart in the rows, and the rows 3 inches from each other. The board D is 9 inches wide, and the holes half an inch apart in the rows, and the rows 3 inches apart; in the board E, the holes are half an inch apart both ways. This board will accommodate 200 lines. Each terminal should be plainly numbered on the board on both sides. If the terminal board can be placed in the roof space instead of in the switch room so much the better. The line-man has only to place the gutta percha lead under the desired number. The connections should be complete down to the switch room, and the annunciators in place when the board is first fixed. This saves the instrument fitter visiting the switch room each time a new subscriber is connected.

The Earth Wire.—Too much importance cannot be attached to having a good earth connection, by means of which the circuit is completed. Some people seem to have an idea that any flimsy attachment, such as twisting a wire round the nearest gas-paraffined wire, a stout wire must be soldered to the water-pipe, and the other wire spliced and soldered to it.

It will in most cases be sufficient if the stout wire used for the earth connection starts from the zinc end of the battery. The connection from the zinc to the instrument can be made with paraffined wire.

The Earth Connection for Exchanges.—If it is so important to secure a good earth on ordinary lines, the same holds good with, if possible, increased force to exchanges, for in the case of the ordinary line that only suffers, but if the exchange earth fails perhaps 500 to 1,000 lines are affected. It is therefore advisable to have several earth connections at various points. If possible a large copper wire such as No. 8 B.W.G. should be used. This should be firmly soldered to both gas and water pipes (on the street side of the meter in the case of gas pipes). Do not trust to any bridging, or any makeshift contrivance, and then there will be no risk of having all the exchange business brought to a stand from "bad earth."

It may sometimes occur that an "earth" has to be obtained where there are no water or gas mains. In this case search must be made for a pump pipe leading into a well, which will make a good "earth." Failing this, however, an artificial earth must be

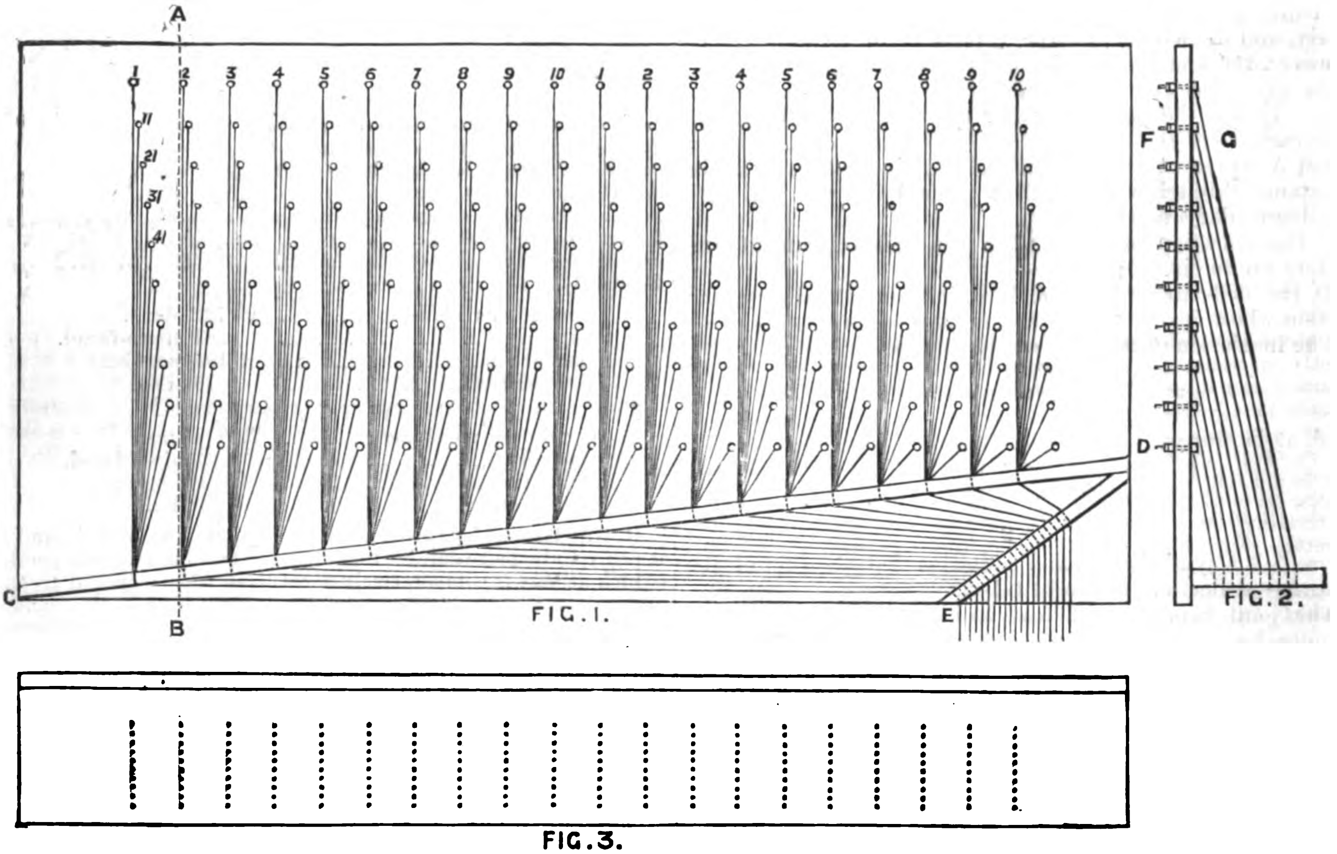


Fig. 1—Elevation of Switch Board; Fig. 2—Section of ditto at A B; Fig. 3—Plan of ditto at C D.

bracket, is sufficient. This, if it answers for a time, is only at the expense of extra battery power, and in all probability causes trouble in calling the exchange, there not being sufficient current passing to drop the annunciator shutter, so, by all means, have a good earth.

If possible, run a gutta percha wire (as used for leads) to the water main (*not a cistern pipe*), scrape the pipe clean, wind the wire (bared of the gutta percha) at least six or eight times round the pipe, bind tightly by drawing the free end under the last three or four coils, and have the whole well soldered together. Failing this, attach to the main gas-pipe, *the street side of the meter* (if on the house side the meter must be bridged over with another piece of wire firmly bound, and soldered on each side), owing to the white or red lead used in the pipe joints making a very bad electrical connection, and composition (*i.e.*, lead) gas pipes should on no account be used. If economy (?) forbids the use of gutta percha covered wire for the earth connection, it is better to use No. 14 or 16 bare copper wire than the small paraffined wire used in connecting up the instruments, because, in all probability, in getting to the water main, the wire must pass places where it will be liable to injury from dampness and other causes; 3-16 galvanised line wire may also be used. If forced to use made thus:—Dig a hole about four feet deep in moist soil (it need not be larger than will enable the workmen to use his tools). Take a strip of about 4lb. of sheet lead, six inches wide and five feet long. Suspend this in the centre of the hole, and fill the hole with tightly-packed gas coke to within six inches of the surface, then fill with the soil to the surface level; the wire must then be soldered to the projecting end of the lead strip.

In some cases where the line is short it may be cheaper to run a second wire and use a metallic circuit.

When testing your earth, test by ringing the bell, and not by the telephone, because the telephone will speak with an "earth" so defective and of such high resistance that the bell could not be made to ring through it.

If it can possibly be avoided, do not have the earth connection on a water main at one end, and on a gas main at the other, as permanent currents are thereby often set up.

The Joining-up Wires.—These usually consist of No. 20 B.W.G. copper wire, having a number of cotton threads laid up parallel with it, the whole well served or bound round with other threads in two colours, so as to show in bands alternately, the whole well saturated with paraffin, and polished by friction. This

Digitized by Google

answers the purpose very well, but the insulation is not proof against wet (especially sal-ammoniac solution), therefore, in joining up the battery, take care that the wires or terminals are not wetted by splashing or otherwise, or a fault, or possibly several, will be surely developed in time.

Do not join the wires unless the joints be soldered; joining is seldom necessary, if a wire should be cut too short do not use it, cut another. The short one will come in another time, and, lastly, *never put two wires under one staple, or allow two staples to touch each other.*

In removing the covering from this or any covered wire, never cut square through the covering, but draw the knife parallel with the wire. The first method in all probability makes a slight nick on the wire, and if this is done the wire will come asunder there if slightly bent, and consequently cause a fault.

Lightning Arresters.—If these are used the earth wire in connection with them should, preferably, be separate from the battery earth wire. It should also consist of No. 16 wire right through, or it will be practically useless. It must be well soldered to the main gas or water pipe.

Although, as a rule, in England lightning arresters are seldom used in exchanges, it may be useful to some who may be engaged in other countries where they are absolutely necessary, to know how to protect the instruments under their charge. In the first place, supposing there are no arresters, and warning is given of the approach of a storm, a stout copper wire may be twisted round terminal after terminal all over the terminal board. This, how-

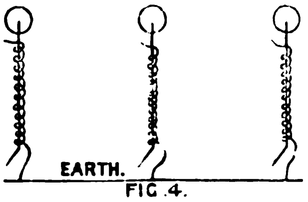

FIG. 4.

ever, stops all operations in the exchange, and must be removed directly the storm is over. The best plan is to insert an arrester to each terminal on the terminal board. A simple arrester may be made thus:—Take two pieces of No. 16 double silk covered copper wire each 6 inches long, and preferably of different colours, twist them firmly together, taking care that the bare ends do not touch each other, test them carefully to see that no leakage takes place between them, fix one end of one wire under the terminal on terminal board, and the end of the other wire to earth. Fig. 4 gives the ideal plan. The two spare ends may be prevented from coming into contact by a covering of sealing wax or shellac. Each line will of course require an arrester. Of course more efficient arresters can be used, but with hundreds of lines the expense is a serious consideration.

The line or earth wires must not be allowed to pass too near lead gas pipes (six inches should be the least distance), as a spark may jump across, fuse the pipe, and fire the gas. This has actually occurred. It should also be remembered that the inductive charge caused by thunder clouds passing over the wires is often powerful enough to fuse the coils of the bells or annunciators, and that short lines are more apt to be affected than long ones.

Lastly, if arresters be used, see that they are carefully made and tested, as there is a risk of communication being interrupted by their leakage to earth.

(TO BE CONTINUED.)

EXPERIMENTAL RESULTS BY SIEMENS AND HALSKE, ON DYNAMO-ELECTRICAL MACHINES WITH CONSTANT TERMINAL E.M.F.

BY ERNST RICHTER.*

The analogy between systems of illumination by gas and by incandescent lamps points to the necessity of contriving some plan under which incandescent lamps may be illuminated and extinguished singly, just as a gas jet may be turned on and off, without affecting the other lights which are fed from the same source. Under the methods hitherto in operation the cutting out of lamps from the system has not been unattended by influence upon the light of the rest, and it has therefore been necessary to counteract this influence by more or less complicated arrangements, as by the introduction of compensating

* Translated from the *Electrotechnische Zeitschrift*, April, 1883.

resistances, which are thrown into the circuit by hand or automatically, by means of electrical regulators, &c.

In the case of an electric machine whose field magnets are excited by a constant current, the brightness of the lamps increases as their number diminishes: and the same thing takes place to a greater degree with machines whose field coils are in a shunt circuit. Lastly, in the case of series machines, as the lamps are gradually taken out the brightness is at first generally increased, then diminishes, and finally sinks so rapidly that below a certain small number the lamps do not burn at all.

If the lamps of any installation are to be capable of being lighted and extinguished singly, they must, in order to be independent of each other, be all arranged in so many parallel circuits, and since the light of each lamp depends upon the difference

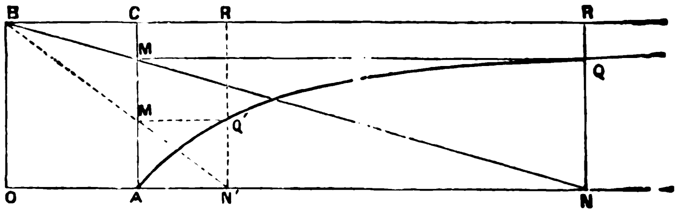

FIG. 1.

of potential at its terminals, they must all possess this E.M.F in the same degree, however many lamps may be in use. In other words, the terminal electrical pressure of the machine at a constant speed must remain constant whatever external resistance is employed. If a machine can be built to satisfy this condition, then all other auxiliary apparatus, whether self-acting or not, will be superfluous, it being only necessary to maintain a constant speed of revolution.

Terminal pressure and E.M.F. are often interchanged and used for one another, but this can properly only be done when the resistance of the machine is so small as to be incomparable with the external resistance, a condition not usually existing. Consequently the E.M.F. of a machine is not constant when the terminal pressure is, and, *vice versâ*, the terminal pressure does not remain the same when the machine possesses a constant E.M.F.

As the question is one of a certain interest it may be well to show how, on the one hand, with a machine with a constant E.M.F., the terminal pressure must change, and how, on the other hand, with a machine whose terminal pressure is maintained constant, the E.M.F. must change.

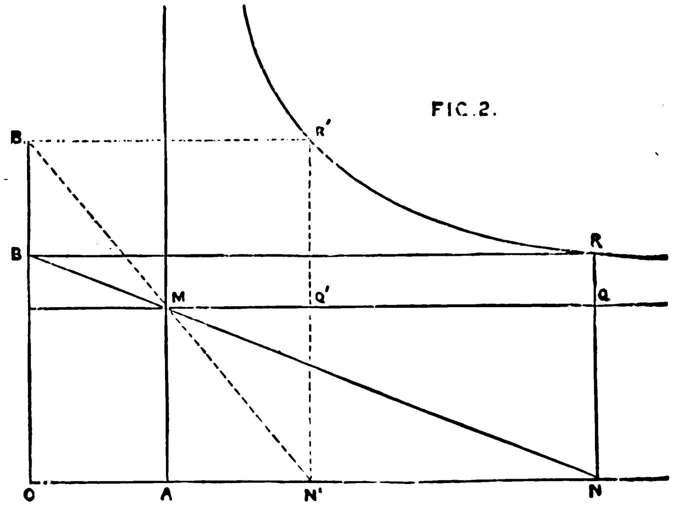

FIG. 2.

(1.) Suppose a machine of constant E.M.F. and internal resistance W_m given. Let the external resistance be W, and the terminal pressure D.

In Fig. 1, if $OA = w_m$, $OB = E$. $AN = w$, then the line BN represents the change of pressure, and $AM = D$. For any other value of w, *e.g.* AN^1, AM^1 represents the terminal pressure. If from every point such as N, a vertical to ON is drawn of such a length as to represent the corresponding value of D, the ends of these verticals will form a curve AQ^1Q, &c., which for all external resistances represents the change in the terminal pressure, while the constant E.M.F. is represented by the horizontal line CR^1R, &c. The equation of the curve of terminal pressure is given by the condition

$$S : w_m = E : (w + w_m) = E : W$$

in which W is the total resistance, and $S = E - D$. From the equation it follows that $SW = EW_m$, that is the product SW is constant, and the curve a rectangular hyperbola, whose asymptotes are the straight lines BO and BR. As the external resistance

Digitized by Google

increases from zero, the terminal pressure increases also from zero, at first quickly, then more slowly, and so as to be asymptotic to the value E.

(2). Now, suppose a machine of constant terminal pressure D, and of internal resistance W_m given. Let the external resistance be w, and the E.M.F. be E.

In Figure 2 if $OA = W_m$, $AM = D$, $AN = w$, then $OB = E$.

For any other value of w, *e.g.*, AN^1, OB^1 represents the required E.M.F. If at every point such as N a vertical to O N is drawn of such a length as to represent the corresponding value of E, the ends of these verticals will form a curve, which represents the change of E.M.F. for all values of the external resistance, while the constant terminal pressure is represented by the horizontal line $M Q^1 Q$, &c.

The equation of the curve of E.M.F. is given by the condition:

$$S : w_m = D : w$$

when $S = E - D$; from which it follows that

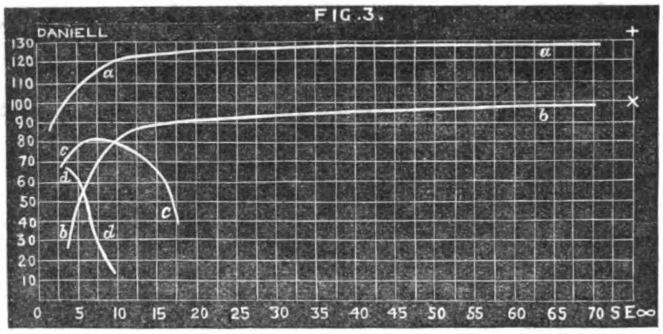
$$S w = D w_m, \text{ or } S w \text{ is a constant,}$$

and the curve is again a rectangular hyperbola, whose asymptotes are the straight lines A M and M Q.

As the external resistance increases from zero, the E.M.F. diminishes from infinity, at first quickly, then more slowly, and so as to be asymptotic to the value D.

Now, to return to the condition described as necessary for incandescent illumination, the terminal pressure, with a constant velocity of rotation, must remain constant under any change of external resistance.

How far this condition has been satisfied in the usual arrangement of electrical machines will be evident from Fig. 3, which represents the curves of terminal pressure in the same machine D_{17} (200) turning with a velocity of 960, under different arrangements of winding and circuit. The curve *a* is plotted under the condition that the field magnets were excited by a constant current of $\frac{17 \text{ Dan.}}{\text{SE}}$. For curve *b*, the electro-magnets were wound with thin wire and put in a shunt parallel with the armature.

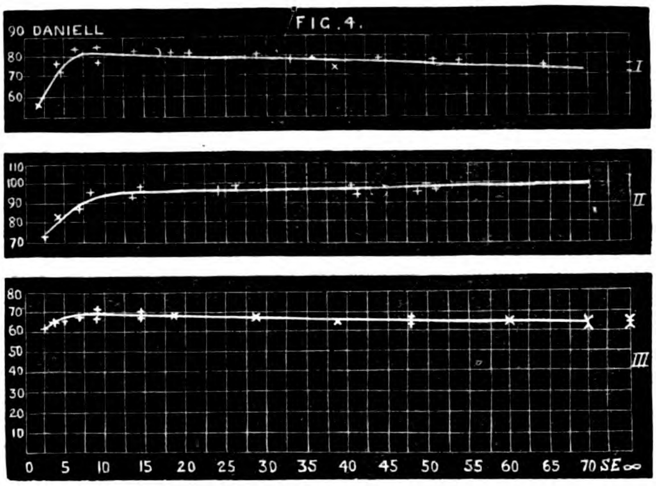


Curve *c* represents the action when the field coils were of thick wire and in series with the moving coils. The ordinates are the measured terminal pressures, the abscissæ the external resistances.

It will be remarked that with an increasing resistance, that is with a diminishing number of lamps, in the curve *b* the pressure increases, that is the brightness of a lamp increases. The curve of terminal pressure of a series machine (curve *c*) changes into curve *d* by an alteration in the winding, and in it the ordinate diminishes with increase of resistance, in contradistinction to curve *b*, in which it increases. The idea to combine these two systems in one machine naturally suggested itself, and hence arose the mixed system of coupling and winding, about which a patent of Messrs. Siemens and Halske was announced on the 20th July, 1882. This patent was withdrawn on the 5th October, as it appeared in the meanwhile that as long ago as 1871 Synsteden, and after him others, had proposed a similar system.

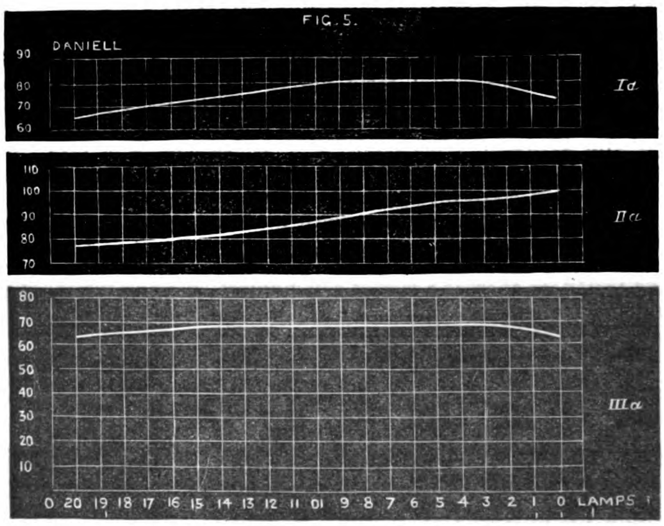
The mixed system has been carried out by Siemens and Halske in various ways. Two of the four electros may receive thin wire, and the other two thick wire, or each of the four may receive two coils, which lie either one over the other, or side by side. The thin wire coils can be coupled parallel with the armature alone, or with the whole machine. The thick wire coil may receive the whole or part of the current. Some of the various results of experimenting with the mixed system of Siemens and Halske are now given.

On the 12th August a dynamo was tested, having two field coils of thin wire, and two of thick. The latter received the whole current, the former were in parallel circuit with the armature. With a fixed speed the terminal pressure was measured, at the same time that the circuit was closed by various external resistances. Curve 1 in Fig. 4 represents the change of terminal pressure, the ordinates representing this quantity, and the abscissæ the external resistances expressed in Siemens's units. The speed was 960. Two cores received each three layers of wire 3·5 mm. diameter, the other two each 19 layers of wire 1·2 mm. diameter. From curve I has been deduced curve I *a* (Fig. 5), in which the abscissæ represent the number of lamps supplied, of 60 Siemens units resistance when warm. This curve is more useful for the present purpose, as it shows clearly how the terminal pressure changes when a given number of lamps are cut out or put in, the number of lamps which give the highest value to the terminal pressure, &c., for which purposes the curves having mere resistances for their abscissæ are not directly serviceable. For representing the external current, the curve having the number



of lamps for abscissæ is also advantageous, for on this plan the curve would more or less approach to a straight line according as the condition of constant terminal pressure was fulfilled more or less perfectly, whereas the curve would approach to a rectangular hyperbola if the external resistances are used for abscissæ.

The curves I and I *a* represent the working of a machine on the 25th August, 1882, before certain members of the German Theatre, and the system of lamps was intended to represent a portion of a theatre installation, in which it is necessary to have the facility of changing at will the number of lamps in use.



On the 3rd September a machine, D_{17} (200), was put to the proof, on which the four cores were each wound with twelve layers of wire of 1·2mm. diameter, and with three layers of wire 3·5mm. diameter. The diagram of the terminal pressure of this machine is represented by curves II. and II.*a*, Figures 4 and 5, and differs from that already considered by continually increasing as the resistance increases, whereas in the former case it falls towards the end. So that with this arrangement the brightness was greatest with one lamp, whereas before it was a maximum with about seven.

On the 10th November the curves III. and III.*a* were given by a machine, D_{17} (200), in which two cores received each two layers of 3·5mm. wire, and the other two each twenty-nine layers of

Digitized by Google

1mm. wire. The action was distinguished by a fairly constant terminal pressure, as can be seen from the curves. This pressure slowly increased as lamps are cut out for about four Daniells, then again sinks, and with one lamp has the same value as with the full number, twenty.

The compound system has been since so developed by Siemens and Halske for smaller and larger machines, even to driving 200 A lamps of Edison, that with a constant speed any number of lamps can be put in or out of the system, without affecting the burning of the others. Lastly, it may be mentioned that a machine, $g\ D_{18}$ (250), on the compound system, has been employed since January 9, 1883, in the reading room of the House of Representatives at Berlin every evening to work thirty-two incandescent lamps of Messrs. Siemens Brothers, of Charlottenburg.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE.*

Foreshadowing of the Electric Telegraph.

Whatever draws me on,
Or sympathy, or some connatural force,
Powerful at greatest distance to unite,
With secret amity, things of like kind,
By secretest conveyance.
Milton, "Paradise Lost," X., 246. 1667.

Amongst the many flights of imagination, by which genius has often anticipated the achievements of her more deliberate and cautious sister, earth-walking reason, none, perhaps, is more striking than the story of the sympathetic needles, which was so prevalent in the sixteenth, seventeenth, and eighteenth centuries, and which so beautifully foreshadowed the invention of the electric telegraph.† This romantic tale had reference to a sort of magnetic telegraph, based on the sympathy which was supposed to exist between needles that had been touched by the same magnet, or loadstone, whereby an intercourse could be maintained between distant friends, since every movement imparted to one needle would immediately induce, by sympathy, similar movements in the other. As a history of telegraphy would be manifestly incomplete without a reference to this fabulous contrivance, we propose to deal with it at some length in the present chapter.

For the first suggestions of the sympathetic needle telegraph we must go back a very long way, probably to the date of the discovery of the magnet's attraction for iron. At any rate, we believe that we have found traces of it in the working of the oracles of Pagan Greece and Rome. Thus we read in Maimbourg's "Histoire d'Arianisme"‡:—

"Whilst Valens [the Roman Emperor] was at Antioch in his third consulship, in the year 370, several Pagans of distinction with the philosophers who were in so great reputation under Julian, not being able to bear that the empire should continue in the hands of the Christians, consulted privately the demons, by the means of conjurations, in order to know the destiny of the emperor, and who should be his successor, persuading themselves that the oracle would name a person who should restore the worship of the gods. For this purpose they made a three-footed stool of laurel in imitation of the tripos at Delphos, upon which having laid a basin of divers metals they placed the twenty-four letters of the alphabet round it; then one of these philosophers, who was a magician, being wrapped up in a large mantle, and his head covered, holding in one hand vervain, and in the other a ring, which hung at the end of a small thread, pronounced some execrable conjurations in order to invoke the devils; at which the three-footed stool turning round, and the ring moving of itself, and turning from one side to the other over the letters, it caused them to fall upon the table and place themselves near each other, whilst the persons who were present set down the like letters in their table-books, till their answer was delivered in heroic verse, which foretold them that their criminal inquiry would cost them their lives, and that the Furies were waiting for the emperor [he was subsequently burnt alive by the Goths] at Mimas, where he was to die of a horrid kind of death; after which the enchanted ring turning about again over the letters, in order to express the name of him who should succeed the emperor, formed first of all these three characters, TH E O; then having added a D to form THEOD the ring stopped, and was not seen to move any more; at which one of the assistants cried out in a transport of joy, 'We must not doubt any longer of it; Theodorus is the person whom the gods appoint for our emperor.'"

If, as it must be admitted, the *modus operandi* is not here very clear, we can still carry back our subject to the same early date, in citing an experiment on magnetic attractions, which was certainly popular in the days of St. Augustine, 354 to 430.

In his "De Civitate Dei," which was written about 413, he tells us that, being one day on a visit to a bishop named Severus, he saw him take a magnetic stone and hold it under a silver plate, on which he had thrown a piece of iron, which followed exactly all the movements of the hand in which the loadstone was held. He adds that, at the time of his writing, he had under his eyes a vessel filled with water, placed on a table six inches thick, and containing a needle floating on cork, which he could move from side to side according to the movements of a magnetic stone held under the table (pp. 718-9 of the Basileae Ed. of 1522).

Leonardus (Camillus), in his "Speculum Lapidum," &c., 1502, *verbo magnes*, refers to this experiment as one familiar to mariners, and Blasius de Vigenere, in his annotations of Livy, says that a letter might be read through a stone wall three feet thick, by guiding, by means of a loadstone or magnet, the needle of a compass over the letters of the alphabet written in the circumference ("Les Cinq Premiers Livres de Tite Live," Paris, 1576).

From such experiments as these the sympathetic telegraph was but a step, involving only the supposition that the same effects might be possible at a greater distance, but when, or by whom, this step was first taken it is now difficult to say. It has been traced back to Baptista Porta, the celebrated Neapolitan philosopher, and in all probability originated with him; for in the same book in which he announces the conceit he describes the above experiment of St. Augustine, and other "wonders of the magnet;" adding that the impostors of his time abused by these means the credulity of the people, by arranging around a basin of water on which a magnet floated certain words to serve as answers to the questions which superstitious persons might put to them on the future.* He then concludes the 21st chapter with the following words, which, so far as yet discovered, contain the first clear enunciation of the sympathetic needle telegraph:—"Lastly, owing to the convenience afforded by the magnet, persons can converse together through long distances." ("Magiae Naturalis," p. 88. Naples, 1558.) In the edition of 1589 he is even more explicit, and says in the preface to the seventh book:—"I do not fear that with a long absent friend, even though he be confined by prison walls, we can communicate what we wish by means of two compass needles circumscribed with an alphabet."

The next person who mentions this curious notion was Daniel Schwenter, who wrote under the assumed name of Johannes Hercules de Sunde. In his "Steganologia et Steganographia," published at Nurnburg in 1600, he says, p. 127:—"Inasmuch as this is a wonderful secret I have hitherto hesitated about divulging it, and for this reason disguised my remarks in the first edition of my book so as only to be understood by learned chemists and physicians. I will now, however, communicate it for the benefit of the lovers of science generally." He then goes on to describe, in true cabalistic fashion, the preparation of the two compasses, the needles of which were to be made diamond-shaped from the same piece of steel and magnetised by the same magnet, or

---

* The author reserves all rights of translation.

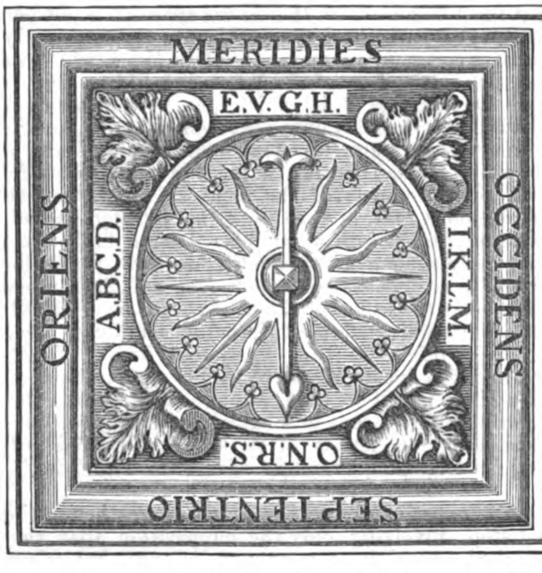
† In the dream of the Elector Frederick of Saxony, in 1517, the curious reader may like to discern another dim glimmering, a more shadowy foreshadowing, of the electric telegraph, whose hosts of iron and copper "pens" reach to-day the furthest ends of the earth. In this strange dream Martin Luther appeared writing upon the door of the Palace Chapel at Wittemburg. The pen with which he wrote seemed so long that its feather-end reached to Rome, and ran full tilt against the Pope's tiara, which his Holiness was at the moment wearing. On seeing the danger the cardinals and princes of the state run up to support the tottering crown, and, one after another, tried to break the pen, but tried in vain. It crackled as if made of iron, and could not be broken. While all were wondering at its strength a loud cry arose, and from the monk's long pen issued forth a host of others.—"Electricity and the Electric Telegraph," by Dr. George Wilson, London, 1852, p. 59.

‡ English translation of 1728, by the Rev. W. Webster.

* While it is generally admitted that magnetism has conferred incalculable benefits on mankind (witness only the mariner's compass), we have never yet seen it stated that it has at the same time contributed more to our bamboozlement than any other, we might almost say all, of the physical sciences. With the charlatans in all ages and nations, its mysterious powers have ever been fruitful sources of imposture, sometimes harmless, sometimes not. Thus, from the iron crook of the Greek shepherd, Magnes, and the magnetic mountains of the geographer, Ptolemy, to the magnetic trains of early railway enthusiasts; from the magnetically protected coffin of Confucius, to the magnetically suspended one of Mahomed; from the magnetic powders and potions of the ancients, and the metal discs, rods, and unguents of the old magnetisers, to the magnetic belts of the new—the modern panacea for all the ills that flesh is heir to; from the magnetic telegraphs of the sixteenth century, to the Gary and Hosmer perpetual motors of the nineteenth, *et hoc genus omne*; all these impostures are, or were, based entirely on the (supposed) force of magnetic attraction, to which must be added an unconscionable amount of ignorance or credulity.

Digitized by Google

rather, magnets, for there were four, (1), Almagrito; (2), Theamedes; (3), Almaslargont; (4), Calamitro; which imparted south, north, east, and west-turning properties respectively to the needles. The compass-cards were divided off into compartments, each containing four letters of the alphabet, and each letter was indicated by the needle pointing from one to four times to the division in which it stood. Thus the letter C would be indicated by three movements of the needle to the first division of the card. The needles were actuated by bar magnets, or chadids, and attention was called by the ringing of a tiny bell, which was so placed in the way of the needle that at each deflection of the latter it was struck, and so continued to ring until removed by the correspondent.



De Sunde's dial as given in Schott's "Schola Styanographica," copied by kind permission of Mr. Latimer Clark.

The next and most widely known relation of the story occurs in the "Prolusiones Academicæ" (lib. II. prol. 6), of Famianus Strada, a learned Italian Jesuit, first published at Rome in 1617, and often reprinted since. Although the idea did not originate with Strada (for he seems to attribute it to Cardinal Bembo, who died about 1547), he was certainly, as Sir Thomas Browne quaintly says, "The *aeolus* that blew it about," for his "Prolusiones" had long been a favourite classic, while the particular poem referring to the loadstone has, if we may say so, been continually going the rounds of the newspapers. It is quoted more or less fully in many authors of the seventeenth and eighteenth centuries, famous amongst whom are Hakewill ("An Apologie or Declaration of the Power and Providence of God in the Government of the World," 1630), Addison (*Spectator*, No. 241, 1711, and *Guardian*, No. 119, 1713), Akenside ("The Pleasures of Imagination," 1744), and "Misographos" (*The Student, or the Oxford and Cambridge Miscellany*, 1750).

The references to it in the present century are simply too numerous to mention. The following is the latest English version:—

"There is a wonderful kind of magnetic stone to which, if you bring in contact several bodies of iron or dial-pins, from thence they will not only derive a force and motion by which they will always try to turn themselves to the bear which shines near the pole, but, also, by a strange method and fashion between each other, as many dial-pins as have touched that stone; you will see them all agree in the same position and motion, so that, if by chance one of these be observed at Rome, another, although it may be removed a long way off, turns itself in the same direction by a secret law of its nature. Therefore try the experiment, if you desire a friend who is at a distance to know anything to whom no letter could get; take a flat smooth disc, describe round the outside edges of the disc stops, and the first letters of the alphabet, in the order in which boys learn them, and place in the centre, lying horizontally, a dial pin that has touched the magnet, so that, turned easily from thence, it can touch each separate letter that you desire. After the pattern of this one, construct another disc, described with a similar margin, and furnished with a pointer of iron—of iron that has received a motion from the same magnet. Let your friend, about to depart, carry this disc with him, and let it be agreed beforehand at what time, or on what days, he shall observe whether the dial-pin trembles, or what it marks with the indicator. These things being thus arranged, if you desire to address your friend secretly, whom a part of the earth separates far from you, bring your hand to the disc, take hold of the movable iron, here you observe the letters arranged round the whole margin, with stops of which there is need for words, hither direct the iron, and touch with the point the separate letters, now this one, and now the other, whilst, by turning the iron round again and again throughout these, you may distinctly express all the sentiments of your mind.

"Strange, but true! the friend who is far distant sees the movable iron tremble without the touch of any one, and to traverse, now in one, now in another direction; he stands attentive, and observes the leading of the iron, and follows, by collecting the letters from each direction, with which being formed into words, he perceives what may be intended, and learns from the iron as his interpreter. Moreover, when he sees the dial-pin stop, he, in his turn, if he thinks of any things to answer, in the same manner by the letters being touched separately writes back to his friend.

"Oh, I wish this mode of writing may become in use, a letter would travel safer and quicker, fearing no plots of robbers and retarding rivers. The prince, with his own hands, might despatch business for himself. We, the race of scribes, escaped from an inky sea, would dedicate the pen to the Shores of Magnet."

(TO BE CONTINUED.)

ELECTRICITY AS A MOTIVE POWER.*

BY PROFESSOR GEORGE FORBES.

The subject of the transmission of power by electricity has been so often discussed in this room that I have had some difficulty in selecting the point of view from which I should look at the subject to night. I presume that most of my audience have seen the action of a current which was generated by one dynamo acting upon another dynamo so as to cause it to rotate. I presume that they have also seen such a motor driving a circular saw, or a fan, or a sewing machine. They may also have heard of the grand possibilities among which the imagination delights to revel, on the realisation of which we shall look back on the old life without electricity as being but one step removed from barbarism. I propose to myself something more humble, but, perhaps, for all that, quite as useful. That is, to discuss the results which have been already attained, and to show what steps are immediately possible with the knowledge and experience now at our disposal. I will not weary you with descriptions of machines, nor refer to their relative merits. In quoting the performance of any special machine, it will not be so much on account of its merit as because it may have come more especially to my notice in connection with the particular subject which I may be talking of.

Of course, from the moment that Oersted discovered the action of a current on a magnet, it was known that energy could be transmitted to great distances by a wire. The energy which is put in at one end of a telegraph cable is partially reproduced thousands of miles away in the form of mechanical movement. But what we have to consider is the condition of using a current to supply motive power to drive machinery. In what cases is such an application practicable, in what cases is it economical, in what cases convenient? I wish to give you, this evening, an answer to these questions, and to explain what has been done and is being done in this field; how far we can build on past experience, and how far we are justified in foreseeing steps in the future. When new discoveries are made, we are distrustful of them; but we are too often, also, apt to be over-sanguine, and dive, in our imaginations, into the future, and conceive that immediately will be accomplished what experience ought to warn us can only be the result of many decades of labour.

Let me give you an example. We are constantly hearing at present of a certain method by means of which water-power, it is said, will be extensively used. This is to use it in charging accumulators with electricity, and then to carry the accumulators on a tramway or railway, and use them to drive the waggons. At first sight this seems very feasible, but reflection makes us pause. The same water-power has been always available; it might have been used to compress air; compressed air tramcars have been constructed, and in my opinion are a perfect success. This method of application of the water-power is much simpler than by the electrical accumulators, but it has not yet been tried, and hence we cannot hope that this method of using electricity is likely to be very soon introduced.

From the time that it was known that a current of electricity in going through a wire round a rod of iron converts the iron

* Paper read before the Society of Arts on Wednesday, May 2, 1883.

Digitized by Google

temporarily into a magnet, inventors have been at work trying to utilise this knowledge in the construction of motors. The chief difficulty lay in the very short distance through which the attraction of a magnet remains powerful. There was also in the motors of old date a difficulty of getting over the dead points. The length of pull of a magnet may be considerably increased by various devices. A somewhat similar action may be effected by utilising the suction of the current through a coil of wire upon a rod of iron. A coil of wire with a current through it acts as a magnet. One end of it attracts the N end of a magnet. But the coil also magnetises a rod of soft iron placed in this position, and having magnetised it, it attracts it.

This principle has been utilised directly to obtain power from electricity. The most interesting application of it which I have seen was at the Electrical Exhibition at Munich last year. That exhibition was especially of interest owing to the various applications of electricity as a motive power, and I shall have occasion to refer to it more than once. The machine to which I now refer is designed by M. Deprez, and is called an electrical hammer. It is intended to perform the same functions as a steam hammer. It consists of a vertical tube containing a short rod of iron, and surrounded with a coil of wire. The wire at each turn is led away to a contact piece on a plate with a movable switch. By this means the current passes only through fifteen turns of the wire. But there are one hundred turns of wire altogether, and by moving the switch you can pass the current through any fifteen you please. You suck the iron into one section, and then move the switch, and so raise the centre of attraction. In this way you suck the iron up to the top of the tube, and then you can equally well drive it down with the force of suction added to the weight of the iron. The weight of the iron was 80lb., the height of the tube one metre. I can illustrate the principle with this model. He used a current of about 36 amperes; 31 amperes was found sufficient when passing fifteen times round to support the weight of the iron. The length of the iron rod was about six times its diameter. This is equivalent to saying that in such a coil a current of one ampere must circulate (15×30^2), or, 13,500 times to support the iron rod in the centre. I tried independently with this small coil, which has three layers of forty-three turns each (129 in all), and I found that five amperes were required to support the iron in the centre. From this result one ampere would have to make 16,200 turns in place of 13,500 as Deprez found. I give these data because they help to fix our ideas, and numerical measurements in magnetism are far more scarce than in electricity. Dr. Werner Siemens has used the same principle in the construction of a motor to be driven by electricity, though I need hardly say his invention was not derived from the one just mentioned. It will readily occur to you that the electrical hammer of M. Deprez might, by a simple modification, be converted into a reciprocating motor, like the piston of a steam engine, and so it might be used to drive a fly-wheel and machinery. But in this mode of applying it, the whole of the momentum of the iron mass would be lost at the end of each stroke. The same is true of the piston of a steam engine. But in the rotary engine it is not the case. Now, although the rotary engine is not so economical as other steam engines, its principle serves to lead us from the electrical hammer of M. Deprez to the beautifully ingenious electric motor of Dr. Werner Siemens. If we suppose the tube with the coil of wire round it to be bent round into a circle, the iron cylinder being also bent into an arc of a circle, then by changing the points of contact for the current to pass through the coils we could suck the iron core round and round inside the circular tube. This is the principle employed by Dr. Werner Siemens in the elegant motor which he has lately produced. The inner iron core is made in the form of a complete ring, but only a certain arc is of iron, the rest is of brass. It rests on wheels, spaces being left in winding the coils for these supports to reach the central ring. In the actual machine the points of contact for the current to enter and leave the coils are changed automatically by the rotating ring. In such a form of motor the magnetism of the iron is never changed or destroyed, and this diminishes largely the waste of energy by heating during magnetising and demagnetising, which is so serious an objection to most motors—I think I might safely say to all other motors.

If this form of motor were used to drive machinery, it is easy to see that, instead of making contact automatically, it would be quite easy to do so by hand, simply turning a handle round; and by doing so, more or less rapidly, the speed of the machinery might be regulated by a boy, with most perfect facility. It could be quickened, slowed, stopped, or reversed, by the simple process of turning the handle. I consider that there will be a great demand in the future for such a form of motor. I will give one example. I am sure many of my audience will sympathise with me when I speak of one of the horrors of a sea-voyage. I refer to the terrors of the steam-winch. What traveller has not spent sleepless nights under the constant influence of the whirring and jarring of that dreadful engine when stowing or discharging cargo. For many years I have felt convinced that this was a field for the application of electricity as a motive power. But for a long time no scheme suggested itself to me which was perfectly satisfactory. In fact, it was not until I saw Dr. Siemens's motor that I felt satisfied that the thing could be accomplished. I have no hesitation in saying that such a motor, with the contacts made by hand, in the manner I have described, will be a very perfect machine, and very much more easily managed than the present steam-winch with its troublesome combination of valves and brakes of multiplying and reversing gear. When such machines are introduced, life on board ship will be a different thing.

Now, I am not going to spend time to-night in describing all the different motors which have been invented. Most motors now in use are simply generators of electricity used in a different way. Many years ago, after a prolonged absence from England in the Pacific, I was writing to the late Professor Clerk Maxwell, and asked him what had been going on in science during my absence. His answer was, "the greatest discovery of late years is that a Gramme machine can be reversed." He saw that this must be a more perfect type of electro-motor than any previous one, and that now there was a real future for employing electricity as a motive power. The Gramme machine was a cheap generator of electricity, and was an efficient motor. The problem was solved, and only required development. Of course, Professor Clerk Maxwell's remarks would have applied to any other of the modern generators. I am not going to trouble you with a description of these machines; their construction is known to most of you. It suffices to say that, when one machine is turned so as to give a current, it can drive another machine at a distance.

Now let me say a few words about the convenience of electrical motors. We are certainly a long way from having electricity laid on to our houses, like water, which we may use for any purpose we please. But when it is laid on, it is certain that many people will use it, because they now use water-engines, although water is very expensive, and because electric motors would be far more convenient in many ways. But in a large factory the only method available for distributing power is either by shafting or by steam-pipes. Both of these are objectionable in many ways, and the convenience of having only to lead wires to the different places where power is required will in time become manifest to many of our manufacturers. This remark applies more especially to donkey-engines and steam-steering apparatus on board ships; and I confiently look forward to electricity being largely used for the light work on steamers, and this before very long. Of course special attention will be given to see that the compasses are not affected by the powerful magnets and currents used for these purposes.

It is found that to get any good effect an electric motor must run at a high speed. In this, there is a great difference between the theory of electro-motors and of steam engines. If a steam locomotive were restrained from running down an incline by the pressure of steam on its piston, the steam would be doing no work, and no power would be used up, except by a slight condensation. But if an electric locomotive were to perform the same office, it would be using up the current all the time, and yet not performing external work. When with the electrical hammer the iron cylinder is supported in the tube by the electric current, power is being used up, and yet no external work is done. It is the same as with muscular exertion. This introduces us to a new factor in mechanics, the cost of the statical effort. When I support a weight, I am using up muscular energy, and yet I am doing no external work.

But there is one peculiarity in electric machines of great importance. The motor is also a generator. Thence it follows that, when it is in motion, it creates an electromotive force. This tends to produce a current of electricity in the circuit, going in the opposite direction to the one which is driving the motor. The intensity of this opposing force is directly proportional to the velocity of rotation. If the generator and motor were identical, and the work done by the motor was so far reduced as to allow it to rotate nearly as fast as the generator, then the opposing electromotive force would almost be equal to that of the generator, and there would be hardly any current in the circuit. But if a brake be put upon the motor, more work is done, and the current in the circuit increases. The maximum amount of work is got from a motor in this way when the counter electromotive force is equal to half that of the generator. The greatest efficiency (or return) is obtained when the counter electromotive force is nearly equal to that of the generator. Some persons have argued from this that we ought to run motors with very light loads for the sake of economy. This is not the case. If the motors were run so as to do only half of the maximum, we should require twice as many motors, and usually the prime cost of the motors

Digitized by Google

is too great to cause this to be economy. The efficiency of a generator for electric lighting or other purposes is highest when there is a very high resistance in the circuit, but electricians, as a matter of fact, nearly always work their dynamos up to their maximum capacity, although this is by no means the most economical, so far as the efficiency is concerned.

(TO BE CONTINUED.)

MEETING OF THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.

MAY 10, 1883.

The proceedings commenced with a description of "The Electric Holophote Course Indicator" by its inventor, Mr. J. H. A. Macdonald, Q.C., associate of the society. This appliance, which was explained and illustrated in our issue of April 8, 1882, is designed to prevent collisions at sea by means of electric light signalling, and not only indicates the course a vessel is steering, but is free from liability of error on the part of the look-out men. An electric light is operated upon in connection with the helm, and to some extent acts automatically in conformity with the tack upon which the vessel is being steered. In view of the greatly increased speed of marine travelling, the crowded state of the courses usually followed, and the unwieldy dimensions of most ocean steamers nowadays, the risks of colliding and the difficulties of avoiding it, while the existing imperfect method of signalling prevails, were daily increasing, and the necessity for some better system was becoming more and more urgent. A penetrating arc light, supplemented in foggy weather by an electric bell, as devised by Mr. Macdonald, would greatly increase the distance between which vessels could sight each other, and would unerringly indicate the course they were respectively steering.

The remainder of the evening was occupied by Professors W. E. Ayrton, F.R.S., and John Perry, who laid before the society the results of a number of recent experiments instituted by them to test the efficiency of electro-motors, and the best method of governing them. The advantages of employing such motors were manifold. They saved gearing and shafting, their distance from the prime mover could be far greater, and their light weight and consequent portability gave them a great superiority. There was still, however, to be determined the best form of motor for given circumstances, and the best means of regulating speed according as the machine was doing little or much work. Many different machines had been tested with a view, first, to find out what relation their power bore to their dimension. The electrical resistance, the mechanical friction, and magnetic friction being ascertained, there remained the useful work given out, which could be ascertained pretty accurately if care were taken to guard against the dynamometer itself causing friction. The first motor examined was the little one called "The Griscom" weighing about two pounds; and this was found to yield 17 per cent. of the power put into it. Of course in this and the following tests it was necessary first to settle what was the greatest power that could be used, that is to say the most powerful current practically applicable without abnormal heating. It was found that current depends on load and speed; and, contrary to what had been stated elsewhere, it also increases with the speed if the load is constant. The next motor examined was one weighing 8lbs., being a Gramme armature with a Siemens field magnet. The efficiency of this was 20 per cent. The Jablochkoff motor yielded only an efficiency of 3·7 per cent, though its weight was two or three times greater than that of the motors previously mentioned, the fact being that well nigh all the faults that could be got into a given space were conspicuously present in this motor. A motor similar to the second one, but weighing 30lbs., showed an efficiency of 26 per cent., in another experiment the efficiency reaching 32 per cent. Thirty per cent. efficiency was obtained from a motor of their own weighing 36lbs., the useful horse-power given out being about a quarter horse-power. Here it became very noticable that while the power per weight of motor increases with the weight to a certain, though not very marked, extent, the efficiency went on increasing enormously as the motors tested became heavier. Another motor of Professors Ayrton and Perry showed an efficiency of 49 per cent., its weight being 75lbs. A De Meritens weighing 72lbs. gave 50 per cent. of efficiency; whilst a large Siemens motor the weight of which was 519lbs., yielded 71 per cent. and in another experiment 75 per cent. The remainder of the discourse was occupied with descriptions of the best form of governor applicable to motors of this class, and with mathematical proof of the correctness of the data arrived at in the several experiments described. Proof was also adduced of the increase in the resistance of an armature due to self-induction—so much so that the armature will stop and revolve in an opposite direction when the current is suddenly cut off. On this point an opinion was strongly expressed that the proportions usually maintained between armatures and field magnets in manufacturing such apparatus are not the best for securing the best results. After the meeting several motors were seen at work, the power for which was supplied by 40 of the half horse-power accumulators kindly lent for the occasion by the Storage Company.

LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).

Report of the directors to be presented at the fifth ordinary general meeting to be held at the offices of the Company on the 31st May:—The balance-sheet and other accounts for the past financial year are submitted herewith; they are made up on the same principle as those last laid before the shareholders. The net revenue of the year, after providing for debenture interest and income-tax, is £9,083 4s. 7d., and £7,583 19s. 6d. is brought from the preceding year's account, making a total of £16,667 4s. 1d. to the credit of the revenue account. The interim dividend of two shillings and sixpence per share, paid on November 19th, 1882, absorbed £4,793 10s., leaving to be dealt with £11,873 14s. 1d., from which the directors propose to appropriate £5,752 4s. in payment of a final dividend of three shillings per share, being at the rate of 2¾ per cent. per annum, and carrying forward £6,121 10s. 1d., pending the collection of the debt due from the Uruguay Government. Active steps are still being taken to induce a proper consideration and settlement of the claim of the Company from that government. The inequitable competition referred to in the last report between the Brazilian Government land lines and the cable system of the Western and Brazilian Company, from which system this Company mainly derives its revenue, still continues. The land line traffic shows a small increase, but the receipts cover an amount not yet paid by the Government of Uruguay for their current messages. The submarine cables and land lines are in good working order. According to the Articles of Association, John Pender, Esq., M.P., a director of the Company, retires by rotation, and offers himself for re-election. Messrs. Deloitte, Dever, Griffiths, and Co., the auditors, retire at this meeting, but being eligible, offer themselves for re-election.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—According to the report of the directors, the receipts for the six months ending 31st December, 1882, amounted to £40,273, and the expenses to £26,693, leaving a balance of £21,201, including £7,621 brought forward. Having in view the small amount of the reserve fund, and the extent of the Company's cables, many of which have been submerged twelve years, the board cannot recommend any payment on account of dividend. They have placed £15,000 to reserve, bringing up that account to £61,843, and recommend that the balance be carried forward. Reference is made to the proposal of the Barbadoes Conference to establish a competing system of cables, which the Home Government has rejected, and it is added that the Company have laid before the Earl of Derby a scheme for strengthening the telegraphic connections of the West Indies.

Digitized by Google

NOTES.

HOLBORN.—The Edison Electric Light Company have withdrawn their application for a provisional order for the Holborn district.

CANADA.—Recent news from the Dominion stated that a committee had adopted the Canada Rapid Telegraph Company Bill, in opposition to the Government.

WIRES AND POLES IN BROOKLYN (NEW YORK).—A recent report states that there are 2,500 miles of wire and over 5,000 telegraph and telephone poles in Brooklyn.

NEW CABLE BETWEEN HONG-KONG AND SHANGHAI.—The Eastern Extension Telegraph Company notify that their new cable between Hong-Kong and Shanghai is now open for traffic.

ELECTRIC LIGHTING IN NEW YORK.—A Bill has passed the New York Senate, authorising the commissioner of the new capitol to complete arrangements for lighting it with electricity.

ANGLO-AMERICAN BRUSH CORPORATION.—It is stated that Lord Thurlow has accepted the chairmanship of this corporation, and that Mr. Herbert C. Gibbs has also joined the Board.

THE ROYAL SOCIETY.—Mr. W. H. Preece, F.R.S., was o read his second paper on "The Effects of Temperature on the Electromotive Force and Resistance of Batteries" before this society on Thursday last.

THE DEVELOPMENT OF ELECTRIC LIGHTING.—This was the title of a paper read on Thursday night, at the Society of Arts, by Mr. J. E. H. Gordon. We shall have more to say about it in our next issue.

SECONDARY BATTERIES.—On Monday last Dr. O. J. Lodge delivered the first of two Cantor Lectures on Secondary Batteries at the Society of Arts. We shall hope to print these lectures at no distant date.

LAND LINES IN CHINA.—A Reuter's telegram dated Hong Kong, April 14, *viâ* San Francisco, says:—"The telegraph line between this city and Canton has been completed, but is not yet open for traffic."

ELECTRIC LIGHTING FOR FULHAM.—The West Middlesex Electric Lighting Company have applied to the Board of Trade for a license to supply electricity for lighting and other purposes in the Fulham District.

TO BE WOUND UP.—A petition for the winding up of the Railway and Electric Appliances Company was presented on the 17th inst., and is to be heard to-day (Saturday) before Vice-Chancellor Sir James Bacon.

ELECTRIC LIGHTING IN LOS ANGELES.—An American contemporary states that the inhabitants of Los Angeles, in California, are highly gratified with the lighting of their city by means of Brush lamps placed on masts 155ft. high.

ELECTRIC LIGHTING FOR THE WEST END.—The St. George's (Hanover-square) Vestry have agreed to support the provisional orders applied for by the Swan and Metropolitan Brush Companies to supply electricity in their parish.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 18th May, 1883, were £1,941, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

M. PHILIPPART.—A telegram from Brussels, dated May 21, says: "The Brussels Court of Appeal has again rejected the demand of M. Philippart to be set provisionally at liberty. This proves that the charges against him are of a very serious nature."

THE TELEPHONE IN PARIS.—On the 1st of this month the number of subscribers to the exchanges of the Societé Générale des Téléphones in Paris was 2,840. The number of calls per week at the same date had risen to 100,000. The number of subscribers to country exchanges was 4,460.

UNDERGROUND WIRES IN NEW YORK.—The Common Council of New York has given permission to the Western Union Telegraph Company to lay its wires under the streets of the city on the payment of one cent. per lineal foot of each street opened and the giving of two wires for the city's use.

ELECTRIC RAILWAY AT FRANKFORT.—It is stated that an electric railway is being constructed between Frankfort-on-the-Main and Offenbach, a neighbouring town, distant about five kilometres (about eight miles). The steam engines and dynamos are to be located at a village named Oberrod, half way between the two towns.

ELECTRIC LIGHT IN MINERAL WATER WORKS.—An installation of a Lumley dynamo machine and sixty Woodhouse and Rawson incandescent lamps has just been put up at Messrs. Barrett's mineral water works by the Lumley Electric Light Co. Messrs. Woodhouse and Rawson were appointed contractors for carrying out the work.

ELECTROLYTIC BALANCE OF CHEMICAL CORROSION.—Dr. G. Gore's papers on this subject read before the Birmingham Philosophical Society have been reprinted from the *Proceedings* of that body in pamphlet form. They occupy some 60 pages of 8vo. An abstract of one of them was given in our issue of 3rd March last, p. 381, Vol. X.

SCIENTIFIC QUESTIONS OF THE PRESENT.—Under the title of "Some Scientific and Technical Questions of the Present" Mr. Julius Springer, of Berlin, has published, in German, some of the more recent addresses and lectures of Sir William Siemens, notably his address as President of the British Association and at the Society of Arts.

A LONG-LIVED LAMP.—A contemporary states, on the authority of the Edison Co., that one of the B (8 candle) lamps used in the Strasburg station installation has been burning over 5,000 hours. The same source also states that the company's manager intends to make a series of experiments with this lamp, and to publish the results.

OVERHEAD WIRES IN WANDSWORTH.—The Wandsworth Board of Works have decided to take counsel's advice as to certain overhead telephone wires that have been erected in their parish, and have also authorised their clerk to agree with the solicitor to the Post Office upon a test case with reference to some of the Department's overhead wires.

PADDINGTON.—After due consideration of the provisional order applied for by the Metropolitan Brush Company, the Paddington Vestry have passed a resolution to the effect that they are of opinion that the question of electric lighting requires further consideration, and empowering their solicitor to take the necessary steps for opposing its introduction into the parish.

THE EDISON SYSTEM IN BRUSSELS.—The Edison Company of Brussels has applied to the municipal authorities of that city for a concession empowering it to light by electricity the interiors in a district which includes several theatres, cafés, and large commercial establishments, but the College of Burgomasters and Echerins has taken time to consider the application.

ELECTRIC RAILWAY COMPANY.—The Electrical Railway Company of the United States was incorporated at Albany, New York on the 8th inst. Amongst the incorporators we

Digitized by Google

notice the name of Thomas A. Edison. The company has been formed to work a system based on the patents of Mr. S. D. Field and Mr. T. A. Edison. The capital is two million dollars.

Appointment.—Mr. W. Hammer has been appointed electrical engineer to the German Edison Co. of Berlin. Mr. Hammer came over to London with the first set of Edison machinery, and took an active part in perfecting the central station on Holborn Viaduct. His energy and ability are well known, and, we have no doubt, will soon be felt in the new field of labour before him.

Electric Lighting in Hartford (America).—The Hartford Electric Light Company has submitted to the city authorities a plan to light the entire city, and the proposition, in official form, will be laid before the council at its meeting two weeks hence. According to this plan a saving of 8,000dols. will be effected, and the city better lighted.—*Sanitary Engineer*, New York.

Electric Lighting for the City.—At the last meeting of the Commissioners of Sewers, the chairman stated, in reply to a question from Mr. Innes, that the question of introducing the electric light into the City was well in hand, that reports were being prepared, and a specification got ready by a gentleman appointed for that purpose, and that in a very short time he thought the matter would be in proper shape for dealing with it.

Sixpenny Telegrams.—A long article on this subject appeared in *The Times*, of the 21st instant, under the heading, "Cheap Telegrams." As the question has been so fully and so frequently treated in our columns we need not make any lengthy extracts from this article. It concludes by advocating the extension of the pneumatic system as offering facilities for an even greater reduction in the rates for the transmission of telegrams.

Incandescent Lamps.—Mr. C. F. Brush has patented a device by which he hopes to preserve the filaments of incandescent lamps from what has been called "molecular bombardment." He inserts a screen of mica between the legs of the filament, and thinks thereby to intercept the minute particles of carbon which are torn off and propelled from one leg against the other, a process which eventually weakens and aids in the destruction of the filament.

The Telephones and Thunderstorms.—Statements have reached us from several different quarters of the alarming and even dangerous phenomena experienced by the users of telephones during a recent thunderstorm. Vivid flashes were seen to emerge from the apparatus, which in some cases was completely disabled. Our informants complain that no proper provision is made to carry the lightning current to earth before it enters the users' premises.

Electric Lighting in Leeds.—At a meeting of the Electric Lighting Committee of the Town Council of Leeds, held on Monday, plans and specifications for the proposed lighting of portions of the new municipal buildings, &c., were submitted and approved, and tenders ordered to be invited. These are to be sent in by the 21st June. As we publish the specification and other information in another part of the paper, we need not refer to this matter at any greater length here.

The Telephone in the East.—The Oriental Telephone Company have transferred their business in Egypt to the Telephone Company of Egypt for £60,000 in 12,000 fully paid-up Ordinary shares and 4,000 Deferred shares in the new undertaking. A company has also been formed in Calcutta to embrace the whole of the Bengal Presidency, and the Oriental will receive in payment for its rights Rs.1,30,000 in cash, Rs.2,50,000 in "A" or Preferred shares, and Rs.3,80,000 in Deferred shares.

Glasgow College of Science and Arts.—The annual distribution of prizes to the students of this college took place on Monday last. The chair was occupied by Mr. J. H Stoddart. The first prize for magnetism and electricity in the Senior Division of the Electrical Engineering Classes was taken by B. Conner, and in the Junior Division by O Rennie and J. R. C. Honeyman, bracketed equal. In electric lighting J. Sharp was first, and in telegraphy, W. Fulton, of the Glasgow Post Office.

Electric Lighting on Ships.—The "Ipswich," which was launched this week at Earle's Engineering and Shipbuilding Company's yard, Hull, is to have all her first class accommodation lighted by means of incandescent lamps. She has been built for the Great Eastern Railway Company's service between Harwich and Rotterdam. This company are always on the look out for anything that can contribute to the comfort of their passengers, and certainly their Continental service is a capital one, as we have often had occasion to find.

Westminster.—The Westminster Board of Works have been engaged in a correspondence warfare with the Board of Trade with reference to an extension of the time for considering provisional orders. The opposition they have offered has drawn down upon them a reminder from the Board of Trade that they are as much bound by the Electric Lighting Act as the companies, and that in the event of such opposition being continued the Board of Trade may have to ride the high horse. The District Board are to hold a special meeting soon to further consider the matter.

The Faure Electric Accumulator Company.—Mr. Harcourt Turner has addressed a circular to the shareholders in this company, reminding them that certain statements made by M. Philippart in December last have not yet been verified. That no date has been fixed for the holding of the annual meeting, although it had been stated that it would be held about the middle of this month. That their chairman is under arrest, and that, with a view, if possible, of determining what is to become of them, he has engaged a room at Cannon-street Hotel, for one o'clock, on the 29th instant, when he hopes as many as can will meet him.

The Czar's Coronation.—The following description of the lighting of the Kremlin was given by the *Daily News* correspondent:—"Early this morning (May 18) I was invited by Mr. Gustav Last, the contractor for the lighting of the Kremlin by electricity, to assist at a dress rehearsal of the illumination. The Ivan Veliki Church was entirely enamelled with 3,500 Edison incandescent lamps, worked at a distance of 1,000 yards by engines of Hornsby and Sons, of Grantham, representing 170 horse-power. As the outline of the cupola began to glow into light the effect was magical, but when the entire church, with its three towers and façade, revealed its full brilliancy it seemed in the black night an incandescent mirage or some strange meteors appearing in the silence of the sleeping city."

New Electrical Commutator.—M. E. Renoult has devised a new key for putting an electrical appliance in circuit, or withdrawing it, without interrupting the current. It consists of two copper plates, insulated by a block of wood, to which they are attached. The main leads are attached, by binding screws or otherwise, to the copper plates at one end, while the other is left free, in the form of a fork, capable of being readily attached to two other copper plates insulated from each other and connected with the leading wires, which

Digitized by Google

put the appliance in circuit. To break contact with these two last-named leads, the fork is withdrawn, while at the same time the circuit is closed by means of a screw carrying on its axis a movable metal plate. In this way the continuity of the current is maintained, while the original resistance is re-established.

INFLUENCE OF TEMPERING ON THE ELECTRICAL RESISTANCE OF GLASS.—M. Jamin lately brought before the Académie des Sciences, Paris, some observations made by M. Foussereau on the influence exercised by the process of tempering on the electrical resistance of glass. The experiments made by this gentleman lead him to the following conclusions:—1. Tempering diminishes, in a considerable degree, the electrical resistance of different varieties of glass. 2. A moderate annealing, sufficient to partially dispel the elasticity due to tempering, diminishes only in a partial degree the influence of tempering on the electrical resistance. 3. The electrical resistance of glass recently annealed continues to increase slowly during a certain period, as if its molecules gradually approached a condition of definite equilibrium; and the electrical resistance of glass, whether tempered or not, which has not been lately heated, remains constant.

NEW EXPERIMENT IN ELECTROLYSIS.—In a recent number of the *Comptes Rendus* M. E. Semmola describes a new experiment in electrolysis. The apparatus consists of a voltameter having three electrodes arranged in the form of an equilateral triangle, with a tube over each electrode. One of the electrodes, *c*, is connected with the positive pole of the battery, the other two, *a* and *b*, being connected with the negative pole by means of a commutator, which is so arranged that the current can be sent entirely through *a* or *b*, or can be separated and sent partly through *a* and partly through *b*. The sum of the volumes of hydrogen collected in the two tubes, when the current is thus separated, is equal to the volume collected in a single tube when the current is sent entirely through one of the electrodes *a* and *b*, thus proving by means of a single voltameter that the same quantity of electricity always produces the same amount of chemical decomposition.

THE PORTRUSH ELECTRIC TRAMWAY.—The *Glasgow Herald* says in a recent issue:—"A few days ago an interesting trial trip took place on the Portrush, Bushmills, and Giant's Causeway Electric Tramway. On the day of trial, when a select company was invited to witness the experiment, the distance from Portrush to Dunluce Castle, three and a quarter miles, and mostly uphill, was covered in 20 minutes, the return journey occupying 14 minutes 30 seconds, which gives an average of 13 miles an hour. The trip was regarded as in every sense successful, and great credit redounds to the engineer-in-chief, Mr. W. A. Traill, for the manner in which he has carried forward the undertaking. His Grace the Lord-Lieutenant (Earl Spencer) has promised to attend the ceremony of the opening run right through from Portrush to Bushmills by means of electricity, which is expected to come off about the beginning of next month." As our readers are aware, the line has been constructed on Messrs. Siemens's system.

VIENNA ELECTRICAL EXHIBITION.—From Vienna we learn that, with a view to facilitate the passage of exhibits through the custom house and from the termini to the exhibition, the committee have entrusted this work to the well-known firm of Schenker and Co., of Vienna. This firm have also branch offices at Budapest, Bucharest, London, Munich, Prague, Tetschen on the Elbe, and Trieste, as well as representatives at Antwerp, Hamburg, Mannheim, Paris, and Rotterdam. Messrs. Schenker and Co. will not only aid the passage of exhibits through the custom house, but will also keep an account of the goods exhibited and sent back after the close of the exhibition, look after the storing of the packages during the time of the exhibition, and give every information to exhibitors as to the forwarding of exhibits. The Italian Ministry of Public Works will be represented by its telegraph administration, and the Danish Admiralty will exhibit some new inventions in the department of torpedoes. The Würtemberg Government has appointed Dr. Dielrich, Professor of Electricity in the Stuttgart Polytechnic School, as its representative at the exhibition.

A SCIENTIFIC VETERAN.—Mr. Mattieu Williams writes in the *Gentleman's Magazine* for this month as follows:—"About a year ago I succeeded with some difficulty in obtaining a copy of an old classical treatise, Chevreul's 'Recherches Chimiques sur le Corps Gras d'Origine Animale,' a series of papers published in a collected form in 1823; and I assumed as a matter of course that the author had long since joined his contemporaries—Cavendish, Priestly, Lavoisier, Wollaston, Davy, Dalton, Berzelius, &c. This is by no means the case, for only the other day he read a paper at the Academy of Sciences, in the course of which he said:—'Moreover, gentlemen, the observation is not a new one to me. I had the honour to mention it here, at a meeting of the academy, on the 10th May, 1812.' Here is a chemist who was born before Phlogiston was dead and buried, when the composition of air and water was newly discovered, and who is, therefore, just as old as modern chemistry, and is now vigorous enough in body and brain to still contribute to its advancement. May his venerable voice long continue to be heard from his old, old place in the Academy!"

UNDERGROUND WIRES.—At a meeting of the Committee on Underground Electrical Communication, the formation of which we noticed in a recent leading article (*Electrician*, May 5), held in New York on the 7th instant, it was resolved to form three sub-committees, in order to deal with the subject in as comprehensive and thorough a manner as possible. The first will confine its attention to the electrical and mechanical difficulties that have to be encountered in laying underground wires, and is instructed to examine the inventions now in use, or that may be presented to it. The committee is also to give notice to inventors as to the nature and extent of the requirements of the case, and to state the problem that has to be solved, with the object of concentrating inventive effort in a practical direction. The second sub-committee will deal with the legal side of the question, while the third, known as the sub-committee on business organisation, is to lay before the general committee a plan of organisation for carrying into effect the recommendations of the two other sub-committees, so soon as they shall have been framed and laid before it, and if necessary to form an independent company for the purpose.

AMALGAMATION OF ZINC FOR BATTERIES.—The usual method of amalgamating zinc plates for galvanic batteries consists in freeing them from oxide by means of acid, immersing them in mercury, and rubbing them with a hard brush. This method, however, has the disadvantages of only depositing a superficial coat of mercury upon the zinc, which is soon denuded by the acids of the battery, so as to require speedy renewal. An electrician connected with the French Department of Posts and Telegraphs has invented a new mode of amalgamation, which is reported to give good results. It consists in immersing the zinc, previously to the usual mer-

Digitized by Google

cury bath, in a solution of mercurial salt, the composition of which is patented by the inventor. This immersion renders the zinc brittle, its fracture presenting a granular appearance, resembling that of dead silver as it is deposited by electro-metallurgy. This new molecular condition permits of the mercury penetrating the zinc, and filling up its pores, and thus forming an obstacle to attack by the acids of the battery. Besides overcoming the difficulties inherent in the usual method of amalgamating zinc, the new process has the advantage of preventing all useless consumption of the metal when out of circuit, and also of preserving a perfect constancy in the battery until the zinc is completely used up.

Injuring Telephone Wires in London.—The charge against Theodore Torrey, manager of the London and Globe Telephone Company, and two of his workmen, of wilfully and maliciously injuring the wires of the United Telephone Company, was again gone into at the Guildhall on Friday week. The workman, James Reynolds, whose evidence we reported in a note in last week's issue, was cross-examined by the London and Globe Company's solicitor, and stated that he did not know who it was gave the order for tying up the United Company's wires, but it was some one in authority, and resembling Mr. Torrey. The wires were tied up for a little time only, about a quarter or half an hour. An order was given to untie them, but by whom he did not know. As far as he could see there was no necessity for tying them up. James Hopkins, employed by the United Company, gave evidence as to seeing Mr. Torrey and Goodfellow pull the wires together and tie them up. Mr. Torrey, as far as he could see, was giving orders. On another occasion he got up on to the party wall of the Wool Exchange, where the tying up was alleged to have been committed, and was ordered off by Mr. Torrey. The men employed there told him at the time that they had tied the wires up because they were in their way. The derrick on the Wool Exchange carried the Globe Company's wires about a foot higher than those of the United Company. The case was again adjourned.

A Welcome to Mr. J. Aylmer.—Those who visited the Paris Exhibition will agree with us that the success of the English section was in a great measure due to the untiring energy of Mr. Aylmer. He was usually one of the first to be found in the well-known pavilion, and certainly did not leave till the last visitor had gone. It was to Mr. Aylmer that visitors fresh to Paris rushed for information. He it was who facilitated all pecuniary arrangements; indeed, his hand and voice seemed ubiquitous in smoothing away difficulties and rendering pleasant and enjoyable, both from a business and a social point of view, the time spent by visitors at Paris. An opportunity was taken on Tuesday last to invite Mr. Aylmer to dinner by a few of those so deeply indebted to him, to show that his services were appreciated, and that kindly recollection of benefits received was duly impressed upon those with whom he had been brought into contact. The invitations were rather hurried, so that many who might have wished to be present were unable to attend. Dinner was served at the Holborn Restaurant, Mr. R. E. Crompton presiding. Among those present we noticed Mr. Edmunds, Mr. A. J. Frost, Professor G. Forbes, Mr. Kapp, Mr. Muller, Mr. Fahie, Mr. Mackie, Mr. Harold Thomson. The toast of the evening was drunk with enthusiasm, and Mr. Aylmer responded. As may be supposed the conversation of the evening dealt principally with anecdotes and reminiscences of Paris experience, and inquiries as to whom we should meet, and what were the prospects of the forthcoming exhibition at Vienna. Our friend Brooks, with his inexhaustible fund of anecdote, was sadly missed, but there was some satisfaction in observing that with a little more experience the mantle of the prophet will fit well the shoulders of Mr. H. Thomson. After the dinner most of the guests adjourned to see the lighting of the Law Courts, and this was the concluding act of a very pleasant programme.

Electrolytic Experiments.—In the *Journal* of the Chemical Society for May is an abstract of a paper by A. Bartoli and G. Papasogli, on the results of the electrolysis of various solutions, which appeared in the *Gazetta*, Vol. XIII., pp. 37-55. From the experiments they have made the authors draw the following general conclusions:—1. In liquids whose electrolysis is not accompanied by evolution of oxygen at the anode, wood charcoal, retort-carbon, and graphite are not disintegrated, and do not suffer any appreciable loss of weight. 2. On the contrary, in liquids whose electrolysis gives rise to liberation of oxygen at the anode, wood charcoal, retort-carbon, and graphite, employed as positive electrodes, are partly disintegrated and partly oxidised to CO and CO_2 (the relative quantities of which depend upon the strength of the current and the superficial area of the positive carbon) together with other products varying according to the nature of the carbon. 3. Graphite used as positive electrode in these liquids never colours the electrolyte, whereas retort-carbon and charcoal previously purified by the action of chlorine at a high temperature colour the liquid deep black, both in alkaline solutions and in those of certain acids and their salts. 4. Charcoal or retort-carbon employed as positive electrode in solutions of acids or of neutral salts whose electrolysis gives rise to evolution of oxygen at that electrode forms chiefly, or rather almost entirely (besides CO and CO_2), a black substance—called by the authors mellogen—whose composition is represented by the formula $C_{14}H_2O_4$, or a multiple thereof, together with mere traces of benzo-carboxylic acids; whilst in solutions of phosphoric acid, hydrofluoric and potassium antimonate a substance is formed analogous to mellogen in its properties, but containing phosphorus, fluorine, or antimony, according to the electrolyte employed. Graphite, on the other hand, employed as positive electrode in the same liquids, produces—in addition to gaseous CO and CO_2—chiefly graphitic acid $C_{14} H_2 O_3$, or an analogous compound containing phosphorus, fluorine, or antimony, according to the nature of the electrolyte. 5. Wood charcoal and retort-carbon, as well as graphite, used as positive electrode in alkaline electrolytes, yield mellic acid $C_{12} H_6 O_{12}$, pyromellic acid $C_{10} H_6 O_8$, hydromellic acid $C_{12} H_{12} O_{12}$, and another body, which is either hydropyromellic acid, $C_{10} H_{10} O_8$, or an acid isomeric therewith.

Legal.—The Telephone Suit.—The case of the United Telephone Company *v.* the London and Globe Telephone and Maintenance Company came before Mr. Justice Pearson on Tuesday last. Mr. Cozens Hardy, Q.C., and Mr. Moulton moved on behalf of the plaintiffs for an injunction to restrain the defendants, their servants, agents, and workmen, from interfering with the telegraph or telephone wires of the plaintiffs, or the supports thereof, or any instruments or apparatus connected therewith, and they asked for an order directing the defendants forthwith to take down or remove any posts or wires or other erections placed or erected by them so as to interfere with any such wires, supports, or apparatus. From the affidavits in support of the plaintiffs' case it appeared that the plaintiffs' company was formed for the purpose of setting up a communication between the houses and offices of the subscribers, so that by ringing a bell fixed at the chief office any subscriber could be put in

Digitized by Google

communication with another, and after they had finished the interchange of messages the communication was broken off. The plaintiffs stated that they had as many as 2,760 subscribers, and the average daily number of messages amounted to 38,000. For the purpose of setting up their wires and poles they had obtained the sanction of the owners of houses and property in their district. It was then stated that the defendants' company was formed in August of last year for the purpose of carrying on a business similar to that of the plaintiffs, and they alleged that in erecting their poles and passing along their wires they had seriously interfered with the wires of the plaintiffs. In some cases they had allowed their wires, through which no messages were at present passed, to rest upon those of the plaintiffs. In other cases they had interfered by means of their poles, and in many instances the defendants' wires were placed so close to those of the plaintiffs that a slight wind, or even change of atmosphere, caused the wires to join together, and to pass the electric current through the wrong wires; but the worst instances of interference were where the defendants had actually coupled together the plaintiffs' wires by means of a band, seventeen in one place, and nineteen in another. The effect of this interference with the plaintiffs' wires was sometimes to cause the bells of subscribers to be rung at the wrong time and place, and sometimes all the bells were set ringing at once, to the great annoyance and injury of the subscribers generally.—Mr. Hemming, Q.C., and Mr. Beale, who appeared for the defendants, asked for time to answer the plaintiffs' affidavits, copies of which had only been furnished to them on the previous day (Monday). They were instructed to say that an answer could be given to all the allegations made by the plaintiffs, but this would necessitate the examination and cross-examination of witnesses, and it would be impossible to prepare the defence in less than a fortnight or three weeks.—Mr. Cozens Hardy, Q.C., submitted that if the case was ordered to stand over for so long a time the defendants ought to be put upon an undertaking either to alter their poles and wires, so as to avoid any interference with the plaintiffs' wires, or they should allow the plaintiffs to do the work themselves, and it was pointed out that there would be no difficulty in doing this at once. If this was not done the injury to the plaintiffs' business might be continued for three weeks or more until the case could be brought on for hearing.—As the defendants did not accede to the plaintiffs' proposal, Mr. Justice Pearson said, under these circumstances, he must treat this as an *ex parte* application, and he should grant an injunction in the terms of the motion to restrain the defendants from interfering with or continuing to interfere with the telegraph or telephone wires of the plaintiffs. The hearing of the motion would then stand over till Thursday fortnight, and the defendants might have liberty to bring on the motion at an earlier period if they preferred to do so.

Electric Light in Liverpool.—A successful installation of six Pilsen dynamos and fifty Pilsen arc lamps has recently been completed at Messrs. Lewis's establishment, Ranelagh-street, Liverpool. This is probably one of the largest installations of arc lights that has yet been made in one building. The work was entrusted to Messrs. Woodhouse and Rawson, electric light engineers, of 11, Queen Victoria-street, E.C., and has given every satisfaction. We may mention that Messrs. Lewis are not by any means new to electric lighting, having for the last two or three years made various experiments with the different systems, and their present house in Manchester has been for the last year or two chiefly lit by Siemens arc lamps. The building in Ranelagh-street consists chiefly of two portions, the old place of business, and a new one, which was opened shortly before Christmas. The latter is a large edifice, consisting of seven stories, basement and sub-basement. The intention was to light up the whole of the building with arc lamps; but, as some of the floors are not occupied, fifteen lights have been temporarily put up in the old building. Here the lights are on the ground floor; in the new building they are distributed over four floors, and over the pavement on the outside of the building. In the basement, which formerly was unbearable when gas was used, four lights have been placed. On the ground floor there are seventeen, including a large 4,000 candle-power lamp in the doorway, which throws a flood of light on to the side show windows and across the street. On the first floor there are six lamps, and in a louvre at the top of the building, which is called the lantern, nine. The effect of these latter, the light from which comes through stained glass sides, is very fine, and can be seen from a considerable distance. Half the sub-basement is at present set apart for engine and machine room. The engine and boiler were supplied by Messrs. Marshall, Sons, and Co. The boiler is of the locomotive type, in which steam can be raised in a very short time to a working pressure of 60lb. The engine is 35 h.-p. nominal, high-pressure horizontal 18in. cylinder, 3ft. stroke, with automatic expansion valve, worked from the governor. It runs at 70 revolutions per minute, and is capable of running about 100 2,000 candle-power lamps. The power is communicated from a 10ft. fly wheel by a treble leather belt, 66ft. long, 20in. broad, to a 4in. steel countershaft, and thence to the dynamos by 6in. belts, all double copper sewn. The dynamos and lamps were made by the Pilsen-Joel and General Electric Light Company. The machines, like those of the Schuckert class, are of the ring armature type, similar to the Gramme, with the exception that the induction of the coils takes place on the lateral vertical faces of the armature, whereas in the Gramme the induction takes place on the horizontal periphery. The machines are wound in series, giving an E.M.F. of about 42 volts per lamp, with a current of about eight amperes. The cables used are seven strands of copper, No. 16 B.W.G., heavily insulated. Above each machine is a German silver resistance board of about 4 ohms, by means of which the external circuit is regulated when required. The leads and returns are taken from each machine to a switch board for the purpose of facilitating change of circuits, as it is often required to run different groups of lamps independent of the circuits upon which they may happen to be. This grouping is materially helped by means of switches arranged in convenient parts of the building. From the switch board the cables pass into an air-shaft, which, running to the top of the building, is used for ventilating the different rooms by means of channels between the ceiling and floor. These channels, which are covered by movable boards screwed down with iron bearers and lugs let into the rafters, carry the cables after they leave the air shaft. This arrangement avoids the appearance of leads on walls and ceilings, a ready access being had to the wires, which are brought down to the lamps through holes in ornamental work, in the centre of which the lamps are hung. The cables for the old building pass right up to the top of the ventilating shaft, and are then carried overhead from roof to roof, and down to the ground-floor to a switch, which is so arranged that eight lights may be run off the 7-light machine during the early part of the afternoon, until the other four are required, when the whole are switched on the 12-light machine from the switch board in the engine room.

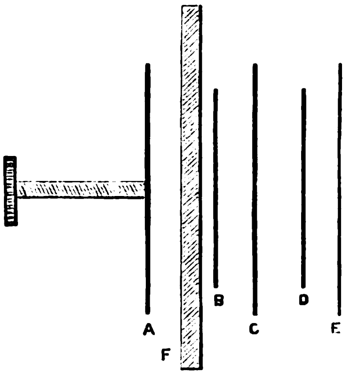
ELEMENTARY ELECTRICITY.—X.

(CONTINUED FROM PAGE 11.)

Gordon's Method of Measuring Specific Inductive Capacity continued.

On introducing between A and B a plate, F, of some dielectric whose specific inductive capacity was greater than unity after the balance had been adjusted, the induction of A upon B became greater than that of E upon D, and to restore the balance it was necessary to remove the plate A to a greater distance from B. By measuring the distance through which the plate was moved, the specific inductive capacity of the dielectric could be determined, for the thickness of the equivalent layer of air could be calculated. A motion of the plate A through ·001in. produced a very perceptible movement in the spot of light reflected from the electrometer mirror. Gordon's experiments gave results varying from 3·108 to 3·838 for different varieties of flint glass, 1·9936 for paraffin, 2·22 for black india rubber, 2·462 for gutta percha, and 2·547 for Chatterton's compound. It is of great importance to obtain accurate determinations of the specific inductive capacities of the insulators employed in the construction of submarine cables, as a high specific



inductive capacity for the insulator means a great electrostatic capacity for the cable, and a corresponding reduction in the speed of signalling.

The fact that in Gordon's apparatus the distances between the plates were not very small in comparison with their diameters introduced great difficulties into the calculations.

Def. The *electric intensity* at a point, or, as it is sometimes called, the *electromotive force at a point*, is the number of units of force which would be experienced by a unit of electricity placed at that point. It has been called electric intensity from the analogy of magnetism and gravitation.

Def. A line of force is a line which, at every point, is in the direction of the resultant force at that point.

The direction of a curved line at any point is the direction of the tangent to the curve at that point.

If a number of electrified bodies be immersed in an insulating liquid, such as paraffin oil, the directions of the lines of force can be exhibited by throwing into the liquid some fine cotton or linen threads, when the conducting threads will take up the directions of the lines of force between the electrified bodies.

Faraday conceived an electric field permeated by lines of force which always proceed from positively to negatively electrified surfaces, taking their origin whenever there is a positive charge and proceeding to an infinite distance unless they meet with a negatively electrified surface. Faraday not only regarded the lines of force as indicating the direction of the resultant force at every point, but he supposed the number of lines of force proceeding from any charged body to be equal to the numerical value of its charge. Maxwell pointed out the analogy between Faraday's lines of force and the "*stream lines*," or lines of flow, in a fluid, and showed that, in virtue of the fundamental law of electrical action, *i.e.*, the law of inverse squares, if lines of force be drawn according to Faraday's system, the number of lines passing through unit area of any surface will be proportional to the force at right angles to that surface, and this will be true wherever the surface may be situated in the electric field.

In hydro-dynamics stream lines are the paths pursued by individual particles of the fluid. In the case of irrotational steady motion these stream lines do not cut themselves, for a particle never returns to the same point, and they do not cut one another, for the fluid being supposed continuous each stream line is completely occupied by its own line of particles, and two particles cannot be at the same point at once. The points at which fluid enters the stream under consideration are called sources; the points at which it leaves the stream are sinks. Stream lines come into existence at sources and disappear at sinks, but are continuous everywhere else; for a particle must preserve a continuous existence from the time that it enters the stream until it disappears. In all cases in which it is a material fluid that is under consideration, the particles must, of course, have come from somewhere when they appear at the source, and must be going somewhere when they disappear at the sink, and it would be possible to trace the stream lines backwards beyond the sources, and forwards beyond the sinks; but if we do not consider the particles until they appear at the sources, and cease to consider them as soon as they reach the sinks, their behaviour is, to us, the same as if they sprang into existence at the source, and went out of existence altogether at the sink. The steady flow of heat through conductors resembles the flow of a liquid, but in this case the heat may really be produced, from some other form of energy, at the source, and may cease to exist, being converted into some other form of energy, at the sink.

If a closed curve be drawn within the substance of a liquid which possesses a steady motion, and through every point in the curve a line of flow be drawn, a tubular surface will be generated. This is called a tube of flow, and the quantity of liquid which passes every section of the tube in a second will be the same. If this quantity be the unit of volume we may call the tube a unit tube of flow. If the whole transverse section of a stream be supposed divided into small areas, across each of which the unit quantity of liquid flows in a second, and if lines of flow be drawn through every point in the boundary lines of these areas, the whole volume of the liquid will be cut up into tubes such that unit volume of liquid passes every section of every tube in a second, that is, into a number of unit tubes of flow. These tubes will exactly fit one another, filling up the whole stream, and never cutting one another; but if there be a source anywhere within the liquid, a number of new tubes will there originate equal to the number of units of volume of liquid sent into the stream in a second, while at a sink a corresponding number of tubes of flow will converge and disappear.

Maxwell showed that precisely the same theorems are true respecting Faraday's lines of force. In place of the volume of liquid flowing across any section of the tube we must substitute the amount of electricity displaced across a thin conducting surface placed at right angles to the tube, and which may be called the induction across the tube. Then, if any electrified area be cut up into contiguous portions, each possessing a unit of positive electricity, and if lines of force be drawn through every point in the boundary lines of these portions, a series of unit tubes of force will be formed exactly filling space without leaving gaps between or intersecting one another. Maxwell showed that the amount of induction measured by the quantity of electricity displaced across a thin conducting surface cutting the tube orthogonally across every section of every tube will be unity, and this is a consequence of the law of inverse squares. At every positively electrified surface tubes of force, in number equal to the charge upon the surface, will spring into existence, and at every negatively electrified surface tubes will disappear equal in number to the measure of the negative charge, so that every positively electrified surface behaves like a source, and every negatively electrified surface like a sink. Everywhere else in the field the lines of force preserved a continuous existence.

Suppose a unit of electricity to be placed within a sphere of unit radius, the electric intensity at every point of the

Digitized by Google

surface of the sphere will be unity. The area of the sphere will be 4π square centimetres, and the product of the area and the electric intensity at any point will, for the whole sphere, be 4π. It is now usual to regard as a unit tube of force a tube such that the area of any section of the tube multiplied by the electric intensity at the section may be unity, the product of any area into the electric intensity in the direction normal to the area is now called the electric induction through the area (*i.e.*, the surface integral of the normal force). The induction through the surface of the unit sphere above mentioned will, on this reckoning, amount to 4π, and its surface should be penetrated by 4π unit tubes of force or of induction. Hence, according to the modern system, every unit of electricity gives birth to 4π unit tubes of force, and from the surface of a conductor charged with q units of electricity $4\pi q$ unit tubes of force will originate and proceed to infinity unless they meet with a negatively charged surface.

If we suppose the unit sphere, having a unit charge at its centre, to be insulated, but made of gold leaf, there will be induced upon its inner surface a unit charge of negative electricity, while a unit charge of positive electricity will be uniformly distributed over its entire surface. These charges being indefinitely near together will neutralise one another's actions everywhere except within the substance of the gold, and thus the force a little way outside the sphere will be the same as before. But this force will be that due simply to the charge on the outside of the sphere, for all the lines of force proceeding from the central charge will be stopped by the negative charge on the interior surface of the sphere. Also the number of units of electricity on each unit area of the outside of the sphere, *i.e.*, the surface density of the electricity on the outside of the sphere, is $\frac{1}{4\pi}$. Since this produces unit force on a unit of electricity in its immediate neighbourhood, it follows that the electric intensity just outside a surface charged with electricity of density ρ is $4\pi\rho$. This result is of importance in connection with the attracted disc electrometers, which will shortly be mentioned.

Maxwell showed that the dielectric will be in equilibrium if we suppose that there is a tension along the lines of force, accompanied by an equal pressure in every direction at right angles to these lines, and that such a distribution of stress will account for all observed electrostatic phenomena. Thus, if lines of force pass from one body to another, there will be an attraction between the bodies represented by the resultant of the tensions along these lines; and we know that such an attraction exists, for the bodies must be electrified oppositely. Again, if two bodies, placed near together, are both positively electrified, lines of force will proceed from each, but the pressure at right angles to the lines causes them to appear to repel one another, and, instead of there being a tension tending to draw the bodies together, there will be a pressure tending to separate them more widely, as if the bodies actually repelled one another. By this hypothesis of stress in a medium, the necessity of assuming a direct action at a distance between the electrified bodies is obviated. When we speak of magnetic lines of force we shall give some illustrations which will apply equally well to electrified systems.

If tubes of force are drawn, in accordance with the system explained above, so that the product of the sectional area of any tube and the electric intensity in the neighbourhood is always unity, such a system of tubes will completely indicate the direction and magnitude of the force acting on a unit of electricity placed anywhere in the field, for the axes of the tubes will be everywhere in the direction of the resultant force, and the sectional area of the tubes will be inversely proportional to the force. Thus the tubes will widen whenever they reach places where the force is weak, and contract in places where the force is strong, just as the stream lines in a river widen out when the river widens and the velocity diminishes, but contract when the bed of the river is narrowed and the velocity of the stream increases, as in approaching rapids.

Since the resultant force is everywhere normal to the equipotential surfaces, it follows that if the tubes of force and equipotential surfaces be drawn for any system the former will be cut by the latter at right angles, and the electric field will be divided into rectangular blocks or cells. Wherever the force is strong the tubes will be narrow, and the equipotential surfaces near together, so that, for both reasons, the cells will be small. Where the force is weak the equipotential surfaces will be far apart, and the tubes wide. If the tubes are drawn according to the system of Faraday, so that the number of tubes proceeding from the surface of a charged body is equal to the number of units of electricity upon the body, and if the equipotential surfaces are drawn for each unit difference of potential, then, as shown by Maxwell, the number of cells into which the electric field is divided will be equal to twice the number of ergs of energy possessed by the system, and each cell will contain half a unit of energy. If the tubes are drawn so that the number proceeding from a charged body is equal to 4π times the measure of its charge, then each cell will contain $\frac{1}{8\pi}$ of the units of energy.

The fact that the energy is proportional to the number of cells suggests the idea that the cells are themselves the receptacles of the energy, that is, that the energy of an electrified system resides in the dielectric. This at once points to a condition of elastic strain existing in the dielectric which is thus rendered capable of being the vehicle of electric stress, and the cause of the apparent attraction or repulsion between electrified bodies as explained above.

Dr. Kerr succeeded in showing that glass and other dielectrics, when exposed to the action of electric forces, are thrown into a state of mechanical strain by transmitting a beam of polarised light through the dielectric at right angles to the lines of electric force. When the Nicol prisms of the polariscope were crossed, and the field dark to commence with, the light reappeared as soon as the electromotive force attained a certain intensity.

Röntgen repeated Dr. Kerr's experiments, employing bisulphide of carbon as the dielectric, and obtained some very beautiful results.

If two parallel plates are placed near to one another but maintained at different potentials, lines of force will proceed from the plate at higher potential to that at lower potential, and, except very near the edges of the plates, these lines of force will be parallel to one another and perpendicular to the plates, for there is no reason why the lines should bend in one direction rather than another. Hence the electric force will be uniform at all points between the plates which are not very near the edges, and the numerical value of the force will be equal to the difference of potential between the plates divided by the distance between them. At points very near the edges of the plates the lines of force will be curved outwards, their lengths will consequently be increased, as well as the distances between them, and the intensity of the force will be correspondingly less; but its exact value is very difficult to calculate.

Sir William Thomson took advantage of the uniformity of the force at all points between two parallel plates, which are not very near their edges, in the construction of the various forms of trap-door electrometer. The essential feature of these electrometers is a disc, or trap-door of metal, which very nearly fits a hole made in the middle of a large metal plate, which is called the "guard-ring." Near this plate or guard-ring is a parallel plate of metal, whose distance from the guard-ring can be altered and measured by means of a screw with a divided circle upon its head. The trap-door is in metallic communication with the guard-ring and is supported, in the absolute electrometer, by springs, and in the portable electrometer by the torsion of a wire, in such a way that its position of equilibrium is a little beyond the plane of the guard-ring. When a difference of potential is produced between the guard-ring and the attracting disc the trap-door is drawn towards the disc with a force depending on the distance between the plates and on their difference of potential. The distance between the plates is then regulated by the screw until the trap-door is drawn into the plane of the guard-ring in opposition to the action of the springs or wire. The distance

Digitized by Google

between the plates is then proportional to the difference of potential. The idiostatic gauge is similar to the portable electrometer, except that the distance between the plates is fixed, the object of the instrument being to determine when the difference of potential attains a fixed standard.

If V denote the difference of potential between the discs of an attracted disc electrometer, and d the distance between them, the electric intensity or force which would act on unit of electricity at any point between the discs will be $\frac{V}{d}$, since V units of work are done on the unit charge in passing over the distance d. Hence the force just beyond the surface of one of the discs is $\frac{V}{d}$. But if the surface density of the electricity upon the disc be denoted by ρ the force must be $4\pi\rho$. Therefore,

$$4\pi\rho = \frac{V}{d},$$

or

$$\rho = \frac{V}{4\pi d}.$$

If A denote the area of the trap-door, the whole charge upon it will be $\frac{AV}{4\pi d}$. To find the force with which the trap-door is attracted to the lower disc we must observe that of the force exerted upon a small charged body placed between the discs one half is due to the action of the upper disc and one half to that of the lower disc, since the discs are equally and oppositely charged and of very large dimensions compared with the distance between them. Hence the attraction of the attracting disc on every unit of electricity upon the trap-door is $\frac{V}{2d}$, and the whole attraction, P, on the trap-door will be equal to the product of this quantity and the charge of the trap-door. Therefore,

$$P = \frac{AV}{4\pi d} \cdot \frac{V}{2d} = \frac{AV^2}{8\pi d^2}.$$

Hence,

$$V = d\sqrt{\frac{8\pi P}{A}},$$

that is, for the same instrument the difference of potential is proportional to the distance between the plates if the attraction P between them is constant.

When we come to consider magnetic lines of force we shall give illustrations of the behaviour of a mass of iron in a magnetic field. The presence of the iron causes the lines of force to be drawn aside from their original directions, so that a large number of lines converge upon and pass through the iron, diverging again from the other side. This effect can be exhibited at once by placing a piece of iron on a card near to a magnet, and then scattering iron filings over the card, when the lines of force depicted by the filings will be seen to converge upon one side of the iron and reappear at the other side. The same action takes place to a greater or less extent when any body whose magnetic inductive capacity or magnetic permeability is greater than that of the surrounding medium is placed in a magnetic field.

A precisely similar phenomenon occurs when a non-conducting body whose specific inductive capacity is greater than that of the surrounding dielectric is introduced into an electric field. The lines of force are drawn aside so that more lines of force pass through the body than originally passed through the space occupied by the body before it was introduced. Thus lines of force will converge upon one side of the body, pass through it, and diverge from the other side. The lines of force become thus concentrated in the body to an extent depending on its specific inductive capacity.

If the body were replaced by a conductor the latter would be electrified by induction negatively on the one side and positively on the other. The lines of force would converge upon the negatively electrified portion and diverge from the positively electrified portion. The effect upon the lines of force in the field is similar to that of the dielectric of high specific inductive capacity, only more marked. As far as its action outside its own substance is concerned, the conductor behaves like a dielectric of infinite specific inductive capacity, while a dielectric of greater specific inductive capacity than the rest of the field behaves like a conductor, but to a less extent; in fact, it behaves as if it had a surface electrification, negative on the one side and positive on the other, but of less density than that which would be induced on a conductor of the same dimensions occupying the same position. Hence the dielectric, like a conductor, will tend to move towards the strongest part of the field, just as a piece of iron tends to move up to the pole of a magnet, and for a precisely similar reason. This is the principle of Boltzmann's method (described last week) of measuring the specific inductive capacities of balls of sulphur ond other dielectrics by the attraction between the balls, and a small charged conductor.

This attraction between a dielectric of great specific inductive capacity and a charged conductor depending on the tension along the lines of force admits of a simple, though only a partial mechanical illustration. Suppose a number of stretched elastic strings to be diverging from a small body, and attached to the walls of the room. Now let a ring be placed so that several of the strings are compelled to pass through it, and are thus drawn much closer together than they would otherwise have been. Between the body from which the strings are diverging and the ring the strings will diverge less than before; but after passing through the ring they will take a turn and diverge more rapidly than before, so as to reach their points of attachment on the walls by as short a path as possible. The effect of the tension of the strings upon the ring will be to force it along the strings towards the body from which the strings are diverging, since this will enable the strings passing through the ring to contract along their length. Thus the ring will be urged towards that portion of space where the strings are naturally closest together. Replace the strings by lines of electric force, the body from which they originate by a positively charged body, the walls of the room to which the remote ends of the strings are attached by a negatively electrified surface forming the boundary of the electric field, and the ring through which some of the strings are drawn by a body of specific inductive capacity greater than the rest of the field, and we have a partial representation of the electrical problem; but we must remember that in the electrical case the lines which correspond to the strings are not only themselves in a state of tension, but behave as though they repelled each other.

CORRESPONDENCE.

ELECTRIC LIGHT FOR NOTHING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There may be, and I take it there is, much of commendable self in our various branches of industry—a sort of weakness to be paid for our work; yet we appear to be approaching more philanthropic principles, demonstrating a pleasing fact, at least to the general public, that there exists in some minds a strong desire to work for nothing, if I may be allowed to judge by a statement in a local paper now under my eye.

This report explains that a local corporate body was desirous of lighting its Town Hall with the electric process; but here is the remarkable feature, that whilst a certain electric company had its honourable estimate for lighting under favourable discussion, a member of the council reminded the committee that "they had an offer from an electric lighting company, close to their own doors, to try the light in the borough free of cost."

Now, sir, I can quite understand that a public company, in its initiating state, before the shares are subscribed for, may light up prominent places gratuitously, and lead an innocent public to suppose the concern to be not only sound, but profitably engaged, and thus secure a good subscription list and much moneys; but why a company that has secured the only object which seems to be the final effort and the only one of most—a large subscribed capital—should offer to light up a large public building for nothing,

Digitized by Google

like the dog in the manger, against the more honest offer of another company, can be only explained by that unscrupulous principle of employing a share capital for purposes ruinous to the general body of proprietors.

Your columns have disclosed within the past few weeks so many cases of maladministration in the management of the funds of public electric companies, so much wide-spread ruin to many an investor, that it is no surprise to me that the system has so greatly suffered in character, and that so many companies are in a condition of semi-liquidation.

There is a great and profitable future for the electric system, but it will not be attained under the present one-sided system of management. W. M.

MICROPHONIC CONTACTS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Many of the phenomenas which are reported by experimenters on loose carbon contacts, notably those in the very interesting observations by Mr. Stroh, are, in my opinion, clearly due to carbon dust on the surface of the solid pieces. It is important that the contact surfaces should be permanent, and very hard and homogeneous, and I beg to suggest that the carbons used for these experiments be carefully washed in clear water, and afterwards dried. Even an apparent smooth surface brought about by polishing is not reliable, and should be tested by washing the surface under water with the finger, or a piece of cloth.

To definitely settle the loose contact transmission, the apparatus ought not only be free of carbon dust, but the current employed ought to be so low and the carbons so hard that no burning can take place. The action by means of detached carbon particles—an arc—is a special phenomenon, and different from a so-called "contact" transmission, and it has ever been the aim of those who first conceived the "contact" principle in telephony to confine themselves to that principle. The time is near at hand when it will be clearly proved that the so-called microphone is merely a contact transmitter of defective mechanical construction, that its name is misapplied, and that the apparent increase in sound is partly due to the scraping of the parts in contact, partly to the fact that the telephone is pressed closely to the ear, and excludes all other sounds. The many theories brought up to explain the microphone, viz., "heat," "arc," "variation of contact area," "number of molecules in contact," "compression of carbon"— all these lack positive proofs, are obscure and confounding, and some have been shown to be wrong; but somehow or other there seems to be in some quarters too much pride to confess that such theories *are* wrong, and the "practical," though less "scientific" workers, who, through laborious experiments had long arrived at the correctness of their own now acknowledged theory, are silently ignored.—Yours, &c.,

E. Berliner,
Chief Inspector American Bell Telephone Company.
Boston, May 9, 1883.

INFORMATION WANTED.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Will your esteemed correspondent and contributor, J. T. Sprague, have the goodness to tell me how to construct a magnetic belt or magneticon, &c. I am very much in want of one, as I suffer very much from rheumatism, and the price charged for belt or body bandage, &c., is so high it is not within my reach at present to get one. Any information from any of your correspondents will oblige.—Yours, &c.,

May 18, 1883. Neuralgia.

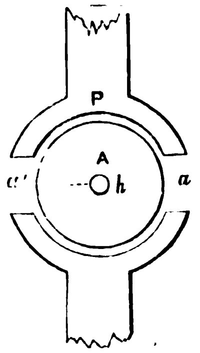
[We insert "Neuralgia's" letter, although we are afraid he will not find Mr. Sprague very ready to tell him how to construct "a magnetic belt or magneticon," seeing that Mr. Sprague views, and justly so, such appliances with but scant favour. "Neuralgia" would, we think, do better in consulting a good doctor.—Ed. *E.*]

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Your correspondents, Mr. Mordey and Mr. Sayers, I have to thank for their courteous criticism of my somewhat imperfect statement concerning the action of the inner wire in the Gramme ring. I did not say all that was in my mind, but I drew a conclusion from a partial statement, which conclusion really came about from a much more extended consideration. I ought perhaps in strictly logical sequence to amend my proposition, and to say that the inner wires of the Gramme ring have no deleterious action on the system; but that would not be quite as far as I would go. With one or two remarks on the proposed experiments I will pass to the description of my own trials, which I hope your correspondents will accept in lieu of more formal argument. The experiment proposed by Mr. Mordey hardly covers the ground. There are clearly two actions (if not more) that may occur in the Gramme ring, (1) the constant approach and retrocession of an element of the ring into and from the magnetic field, (2) the cutting of lines of force by the wires of the ring. Now, my contention is that from these two causes of E.M.F. in the coils of the ring the first is by so far the greater that *in practice* the second may be neglected. Considered apart, I have no doubt that the experiment proposed by Mr. Mordey would be strongly in favour of (2), and that the lines of force cut *are* greater on the one side of the ring than the other, but the greatest E.M.F. is undoubtedly due to (1), or the determination of the lines of force into the iron of the ring considered as a circular electro-magnet.

My attention was first drawn to this by the following experiment, made for another purpose, viz., that of ascertaining the best size of pole-piece. I took a Gramme ring, A, and surrounded it with the long horns of a heavy pole-piece, P.



Between the ends of the horns *aa* there was a heavy discharge of lines of magnetic force. I maintained in all the following alterations the strength or intensity of the magnetic pole P *constant* by changing the amount of current passed around the coils on P, measured by Du Moncel's method of approaching a solenoid to the pole at constant speed. The speed of revolution of the ring A was also kept as constant as possible. The horns were then shortened and the E.M.F. increased. At about *h* I expected the E.M.F. to remain constant, but it increased until no horn remained, and the pole-piece was of same size as core of magnet. [I want it understood that the magnets were separately excited, and that the increased magnetic intensity consequent upon decreasing the volume of the pole-piece was compensated for, as measured as described, by reducing the current.] Whence it appeared to me that very little E.M.F. could be due to cutting of lines of force between pole-piece and ring, and that this must depend on the strength of the pole induced in the ring.

I afterwards found that the section of the electro-magnet should be twice the section of the ring to give, experimentally, the best results as regards E.M.F., that is, with a Gramme ring; with the Pacinnotti ring the results are not quite the same.

Subsequently I tried to verify these results by winding a ring the width of which was half its diameter, first as a drum, then as a Gramme ring. In the first case, where the winding was as a drum, I got an E.M.F., equivalent, at the

Digitized by Google

speed, to the length of wire passing over the width of the drum. [I need scarcely point out that the E.M.F. is independent of resistance.] I then wound the wire as in a Gramme ring, and got immediately *nearly* twice the E.M.F.; had this inner wire been inert I should have had no increase.

Next I dismounted a Schuckert machine, and causing the magnets to be set up on one side only of the ring, I revolved the ring at constant speed, and put current on to the magnets till there was no increase of E.M.F. I then caused the magnets on the other side to be set up and added; the increase of E.M.F. was about 2 to 3 per cent. Evidently the cutting of lines of force, although in this case not so conclusively negative in this last result, cannot be said to be the chief cause of the current in the Gramme ring, *in practice*.—Yours, &c., PAGET HIGGS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In my letter, published on page 16 of your last week's issue, second column, line 13, the word *course* should read *cause*.—Yours, &c., W. B. SAYERS.

May 19, 1883.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your correspondent "Good Earth," in your impression of 21st April last, asks a very important question regarding the earth resistance of lightning conductors, which I hoped would be answered before this by some one with large experience in that branch of electrical testing. I trust some one will yet be disposed to do so for the benefit of many of your readers who are interested in the subject. Meantime I give you some results I obtained last year in testing the conductors of three factory chimneys, which I trust will prove useful.

I found that No. 1 on several trials had a resistance of 42·9 ohms. Thinking this much too high, I got the earth end lifted. It consisted of only 6ft. of the conductor with the end untwisted about 6in., buried 3ft. below the surface in dry soil at the base of the chimney. In order to improve the "earth," I had a copper band, of greater area than the conductor, fastened round an iron water pipe 15in. diameter, which passed near the chimney. The band was drawn up tight with a bolt, and common solder sweated in between the band and pipe, over an area of some square inches. The conductor was then laced through holes in one end of the band, which projected for the purpose, and carefully soldered. Tests now showed that the resistance had fallen to about ·6 ohm. It varied between ·46 and ·75. I have tested this conductor again to-day, and find the resistance to be ·26 ohm for "earth."

No. 2 conductor had 4·37 ohms resistance. Compared with No. 1 this was a poor "earth." It was therefore lifted, and found to consist of about 16ft. of the $\frac{1}{2}$in. copper rope buried in dry soil. It was "re-earthed" by splicing and soldering to one end of another piece of conductor, which was led about 40ft. distant to a deep well, into which the other end was dropped about 7ft. This alteration had the effect of reducing the resistance to ·38 and ·42 ohm. Thinking the "earth" might be still further improved by soldering the hose end to a 5in. iron pipe in the well, the latter having a very large surface contact, it was connected by copper band in the same manner as No. 1, but the resistance became somewhat greater, viz., ·6—·7 ohm. The bare conductor submerged in water seems to be the best "earth."

No. 3 was a new conductor just erected. It consisted of a copper rope $\frac{5}{8}$in. diameter in two pieces. The earth piece was soldered by means of a copper band, as before, to an iron pipe 15in. diameter, and 20ft. below the surface. The earth resistance measured in this piece alone was ·66 to 1·25 ohm. It was then spliced to the conductor on the chimney, and the joint well soldered. On again testing so that the splice was included in the circuit the resistance was ·74 to ·86 ohm.

As great care was taken in making these "earths," I concluded they were the best possible. I am now glad to find a confirmation of this in their close agreement with that o the conductor recently erected on the General Assembly Hall at Edinburgh, where the earth resistance seems to have been about ·7 ohm.

Your report of the tests of this conductor is interesting as being the first instance I have met with in which a figure is given for a *good* earth resistance. Surely this point is not intentionally withheld. Yet I have looked at text books on electricity and electrical testing and find no mention of it. I have read Anderson's book on "Lightning Conductors," Wilson's little book on "Factory Chimneys and Conductors," as well as the "Report of the Lightning Rod Committee" appointed to collect information of this kind, and although all of these authorities speak of the importance of making conductors terminate in "good earth," of having them periodically tested, and even figure a special instrument for testing, not one of them give the slightest hint as to what "good earth" is!—Yours, &c., T. L. P.

Greenock, 22nd May, 1883.

TELEPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The observations I made on metal microphones of the hammer and anvil type were meant to apply generally, and not to Mr. Theiler's instruments in particular. I should be sorry to disparage his or any other instrument intentionally, and I am pleased to find that he has succeeded in overcoming the "stiction" on which too much stress has been laid since Mr. Bidwell's experiments and inference. Being an advocate for the possibilities of metal microphones, I am not disposed to question Mr. Theiler's success, though *a priori* I had grave doubts about it, for the reasons formerly given. By wasting of the "points," I, of course, meant the contact points or surfaces, which every metal microphone must have.—Yours, &c., J. MUNRO.

DOUBLE WOUND DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Ernst Richter, in your last issue, mentions that the double winding of dynamo-machine magnets has been described by Sinsteden in 1871. Will any of your readers kindly refer me to the description of this double winding on *separate* cores? This arrangement was patented by me in 1881, and in work early in that year, and I really fail to find that Sinsteden does more than merely indicate a double winding on the *same* core, an arrangement that, as shown by the able diagrams of Mr. Richter, does not give nearly so perfect regulation, and besides has several disadvantages as regards induction.—Yours, &c., PAGET HIGGS.

THE LIGHTING OF NOTTINGHAM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you kindly correct the following error which appeared in my letter to you of the 17th of May.

For 4d. per horse-power per hour it should be ·4 or $\frac{4}{10}$d. per horse-power per hour.—Yours, &c.,

R. E. CROMPTON.

PRACTICAL TELEPHONY.

(CONTINUED FROM PAGE 19.)

GALVANOMETERS.—The kind most in use are known as detectors, in which the needle hangs vertically, the lower end being weighted. As, however, it is at times more convenient to use the instrument on its back, dial upwards, it is preferable that the needle be kept to zero by a small directing magnet, instead of the end of the needle being weighted. Its position is then of no moment, and the magnet may also be removed, whereby the sensitiveness of the instrument is much increased. When the magnet is removed the instrument must be turned till the needle points to zero.

It is also an advantage to have the scale on the lower half of the dial instead of the upper, where it is frequently hidden by the

Digitized by Google

brass rim that holds the glass, when used standing on the ground. These instruments should be wound for quantity and intensity, as they are usually termed, the quantity or short coil wire consisting of a single layer of thick wire, and having a very low resistance, the intensity or long coil wire being very fine, and having a resistance of 150 to 200 ohms.

It much increases the utility of this instrument if the fine wire, or intensity coils, are provided with a shunt having one-ninth of their resistance, so that only one-tenth of the current passes the intensity coils when the shunt is in circuit. A small switch must be provided to put the shunt in or out of circuit. Detectors are now made having these improvements.

In addition to a supply of detectors, each office should have a horizontal astatic galvanometer to use with the Wheatstone bridge coils, this form being much more sensitive than the detector, the needles being carefully balanced, and the holes jewelled to reduce friction.

As its needle is kept in position by the earth's magnetism, the instrument must be turned so as to bring the needle to zero.

A small magnet is usually supplied with these instruments, which can be laid on the table some distance away, either to reduce or increase the sensitiveness of the instrument, the reduction or increase depending whether the north pole of the magnet is attracting, or repelling, the internal needle; to increase the sensitiveness the position of the magnet should be such, that the needle just returns to zero after having been deflected, and yet if it be placed the least closer, it drives or repels the needle from zero.

There are numerous other forms of galvanometers, but the above two instruments are sufficient for all ordinary purposes.

It may be as well to mention that the graduation on the scale is not proportioned to the amount of current flowing, it is fairly correct up to 20°, but as the needle moves further from parallelism with the coils, the effect of the current gets less and less, and at right angles, or 90°, it is practically *nil*. As detectors vary so much, it is useless to give any table of deflections for a certain amount of current, but each instrument can be tested, and the deflection when connected to a good cell noted for future use (the thick wire coils *must* be used for this test, as a very bad cell will give a good deflection through the fine wire coils).

THE BATTERY.—Our remarks will be confined to the two forms that in actual use have proved to be the best for telephonic purposes. For all private lines and the batteries at exchange subscribers' premises the prism form of Leclanché (No. 2 size) is the best. The number of cells used is usually four. The ringing battery at exchanges should consist of at least six cells, and each table should have a separate battery. The following is a description of this battery, with instructions for maintaining it in good order:—

The negative element of the old form of Leclanché cell is composed of a carbon plate placed in a mixture of coarsely powdered peroxide of manganese and carbon, the whole contained in a porous cell. The positive element consists of amalgamated zinc. The exciting liquid is a solution of sal-ammoniac. The solution has no chemical action either on the zinc or the peroxide of manganese so long as the cell is not at work. This is a great advantage, but the cell with the porous pot offers a rather high resistance, and the late M. Leclanché had for some time past been experimenting with a view to improvement. This he succeeded in effecting in the agglomerate form of cell by substituting movable plates for the porous pots. The materials used to form the depolarising plates are, in course of manufacture, submitted to a pressure of several tons, and, when joined to a carbon plate, compose the negative element of the cell. To fit up the agglomerate cells, place against each side of the carbon plate an agglomerate block, and stretch over them the two india rubber bands. These bands have each a solid part through which a hole has been bored to receive the zinc rod. By this means the zinc is kept from touching the negative element, thus avoiding injurious local action, the whole is held firmly together, and is ready to be placed in the glass jar.

The following quantities of sal-ammoniac should be used to charge the battery: For a No. 3 (small size) cell, 4oz.; for a No. 2 (medium size) cell, 6oz.; for a No. 1 (large size) cell, 10oz. In each case the cell should be filled with water so as to cover the agglomerate plates. If the cell is required for immediate action, the solution mixed in the above proportions should be prepared before being poured into the cell. The advantages of the new cell with agglomerate plates (as stated by the manufacturers) may be enumerated as follows:—

1. A much better use is made of the depolarising power of the manganese, as the reduction of it is more complete than in the porous pot form, where the manganese while being reduced clogs and prevents the action of the battery long before the whole of the manganese is reduced.

2. In consequence of the readier reduction of the manganese, the carbon plate is more rapidly depolarised than with the porous pot form, and consequently the electromotive force is more sustained.

3. The resistance is *extremely constant*, whatever the electrochemical work done by the cell may be, and will even tend to decrease in consequence of the formation of chloride of zinc, which is an excellent conductor.

4. The battery is ready for use immediately on charging, because the liquid is brought into direct contact with the negative and positive elements.

5. The renewal is exceedingly simple. When the battery becomes exhausted, the depolarising plates which are joined to the carbon plate have only to be removed, and fresh ones substituted.

6. By avoiding the use of porous pots the risk of breakage and deterioration is very much lessened, and the cost of renewal considerably reduced.

7. The trouble and cost of maintenance are next to nothing.

The Leclanché batteries are connected up like all other batteries—that is, the carbon of the first cell is left free, and the zinc is connected to the carbon of the second cell, the zinc of which is connected to the carbon of the third cell, and so on to the last cell, the zinc of which remains free, as shown in a future diagram of connections. When the two poles of the Leclanché battery are brought together, or, in other words, when the battery is at work, the solution of chloride of ammonium (sal-ammoniac) is decomposed, and an oxy chloride of zinc is formed, which is soluble in the surrounding liquid. The hydrogen and the ammonia go to the negative element, and are absorbed by the peroxide of manganese.

It is important that pure sal-ammoniac be used, as the impurities found in ordinary sal-ammoniac tend to cause a rapid consumption of the zinc rods.

Although the battery works well under ordinary conditions, the best results are obtained when the following precautions are taken:—

1. Keep the cells in a dry place of medium temperature.

2. Rub the inside of the neck of the glass cell (if it has not been previously paraffined) with oil or tallow, to prevent the possible creeping of the salts.

3. Take care that the contacts are always clean, and that the conducting wires are efficiently insulated.

4. When through evaporation the level of the water has fallen below the top of the agglomerate plates fresh water should be added.

5. If the liquid becomes milky or opaque, add sal-ammoniac until the liquid becomes clear again, or substitute a fresh solution.

6. Scrape the crystals off which sometimes settle on the zincs.

7. When inspecting see that no white lead is forming between the lead cap and carbon. If there is, the cells must be removed.

8. See that none of the solution gets on to the wires or terminals, it being very destructive, and rapidly causes a fault.

If care is taken in observing these precautions the battery cannot fail to give satisfaction. In exchanges where the work is very heavy the ringing battery had better consist of 6 to 8 gravity cells. These may be made as follows:—A glass jar 10in. high and 9in. diameter fitted with a porcelain or wood cover saturated with melted paraffin, a circular zinc ring with two projections cast on it which come through holes in the cover, and are held in this position by pins. One of these projections is fitted with a brass screw terminal, and, lastly, an inverted funnel made from 4lb. sheet lead pierced with holes. We shall show how the whole is placed in position in a future diagram.

To charge this battery drop copper sulphate down the neck of the funnel till it is full, then add pure cold water till it covers the zinc ring; the battery can then be joined up in the usual manner, *i.e.*, the strip of lead from the neck of the funnel going under the binding screw of the next zinc ring, and so on in succession. The last lead strip and zinc ring may then be joined by a wire, so as to short circuit the battery, and left thus for twelve hours. By that time the lead funnel will be found covered with copper, deposited from the sulphate, and so converted into the copper or negative element of the cell.

The only attention these cells require is:—Keeping the funnel neck full of sulphate, occasionally taking out the zinc and scraping off the copper deposit, and drawing off by means of a syringe some of the solution, replacing it with sufficient water to cover the zinc. Do not shake the battery after it is once in action.

The Leclanché cells may in all cases be retained for the transmitter local cell.

Always keep batteries in the coolest possible place (provided frost cannot reach them). Therefore the floor or a low shelf is preferable to their being placed near the ceiling. If obliged to put them in a warm place inspect more frequently.

(TO BE CONTINUED.)

MORE TELEPHONIC BATTLE.

Just when intelligence reaches us from the United States that a serious attempt is to be made to solve what American electricians call the "underground problem," we on this side of the Atlantic are attempting a solution of the overhead problem in a manner not at all serious, but, as one may venture to call it, rather frivolous. The proceedings at the Guildhall last Wednesday week, in the matter of two competing companies doing battle, so to speak, on the housetops, at the imminent risk of committing manslaughter, reveal a state of things which is happily rare in this country. There was, no doubt, a considerable amount of science displayed by the combatants, but it was not exactly of the electrical sort, and it contributed very little to the solution, scientifically, of any problem whatsoever. If the squabble the particulars of which Mr. Alderman Stone had to listen to with a grave countenance were not so amusing, we should be inclined to call it scandalous. It is really disgraceful that telephone wires should be liable to be wilfully tied together; and it is extremely unfair to users that their bells should all be set ringing by a powerful current impartially, but wantonly, distributed among those wires. At least, it would be disgraceful if it were a malicious act; but, in the absence of malice, its comic aspect remains uppermost, and as the comedy stopped short of a tragic ending, we are, on the whole, disposed to laugh at it.

Into the merits of this particular dispute we have no desire to travel, and, indeed, we know little or nothing of the merits of either of the parties concerned. Of their demerits we do know something, and will speak of them presently. But we are justified in joining in the laugh which a witness deposed to having been indulged in by the defendants' workmen when they playfully set the bells a-ringing belonging to the complainants. Proceedings were taken under the Malicious Damage to Property Act, probably because no other Act exists for the protection of property of the kind in question under which action could be taken. They are not Post Office wires, and are not, we should suppose, covered by the provisions of the Telegraph Act. At all events, the defendant company pleaded that the case was one for the Court of Chancery, not for the police court, and the suggestion may be taken as a repudiation of malice in the ordinary meaning of that term. There was a pretty suit going on in the first-named court, a suit which had already cost the litigants some £30,000, and evidently these *ex parte* proceedings on the top of the Wool Exchange were a mere episode in the main business which it was simply undignified to bring into an inferior court at Guildhall.

Such, at least, seems to have been the view of defending counsel, as advised by his clients. Possibly it is not a view that will be acceptable in English law. We have always frankly owned our indebtedness to America for the discovery of the telephone; we shall be equally prompt to acknowledge our obligation—such as it is—to the same country for a novel way of testing telephonic rights. It is not an English invention, but we shall be ready to adopt it if it prove successful. For, in sober earnest, we are exceedingly anxious to learn whether these telephonic companies, or any other companies who may shortly be expected to compete with the existing ones in the art of carrying wires over housetops and across leading thoroughfares, have any rights at all, and, if so, to have them clearly defined. It would appear that some people fancy they have exclusive right to the sky above any building on which a "derrick" of wires is erected, and that nobody else's wires may cross them. We sincerely hope the fancy may prove reality, for then there will be some limit—a wide limit, it is true, but still a limit—to the ever-increasing entanglement of overhead wires. We know that at present no place is too sacred, no place too dangerous, none too beautiful, for telephone interests to profane, imperil, or disfigure. But if it turned out that there are some which it would be *unlawful* for them to invade we should be thankful. It would really be a good investment for parish authorities, failing all other hindrance, to run a wire along either margin of the few thoroughfares not yet invaded by the telephone companies in order to prevent them crossing from side to side. We wish the Court of Chancery would solve this knotty legal problem with less than its accustomed slowness.

Meanwhile, we can see no escape from the nuisance of the

Digitized by Google

overhead wire, except by removing it out of sight, as suggested at the meeting of the New York "Underground Committee." Unlike the overhead committee, whose abortive meeting on a roof adjoining Coleman-street, London, we referred to above, the New York committee arrived at unanimous conclusions after amicable discussion. It was resolved, first, that the public and the corporations desire to "relieve the thoroughfares from poles and wires." As a statement of fact this is valuable testimony from a city where the resources of civilisation are not generally objected to on the score of their hideousness. Secondly, it was affirmed that the time has arrived when it was expedient to make "an exhaustive examination of all devices and inventions pertaining to the subject of underground electrical communication, with a view to determine whether any inclusive system can be found" to establish such communication. An inclusive system, we take it, means a scheme of underground channels where every electrical wire can be lodged safe from the interference of over-zealous workmen in the employ of competing companies, from the risk of killing inoffensive citizens, and from the possible pecuniary danger of exasperating public opinion to such a pitch that the wires will receive summary orders to quit before any other receptacle is provided for them. On the whole, we are inclined to hope most from the New York method; but the London device may prove useful, to a certain extent, in the same direction, though by no means intended to be so.

THE LIGHTING OF THE REFORM CLUB.

The electric light is gradually winning its way, and as its excellencies are tested by experience its use will increase. There must necessarily be ups and downs, doubts and fears, but if the thing is of value it will assert its value. Club land is somewhat exclusive, and an examination of a new method of lighting not an easy matter to arrange. The Reform Club, however, is giving the system a trial. The dynamo used is the Elphinstone-Vincent 400 light shunt-wound machine, which is said to be nearly self-regulating, so that lamps may be turned on or off at will. This machine, we are told, was selected because it is calculated to supply sufficient current to lamps for the whole lighting of the club, and that if a non-regulating machine was used, the engine being old, and hardly adapted for such work, would increase the unsteadiness of the light. A secondary battery has been provided to obviate any unsteadiness, but has not been required. The motor is an Easton table engine, about six horse-power, hitherto used for pumping water, working a lift, &c., and overhauled for these experiments. With forty lamps the steam pressure is 38lb. per square inch. At first one end of the dining room, and the corresponding end of the library just above were lighted with twenty Swan lamps in each room. The lamps were arranged in a ring, and suspended about 14ft. from the floor. These lamps have been replaced by fifteen Woodhouse and Rawson lamps, with ground glass globes, and it is found that there is abundance of light. The walls of the library are covered with books, and the ceilings and pilasters are coloured olive green, relieved with much gilt carved work. A larger number of lamps could, therefore, be used, and in this room the naked lamps bring out the beauties of the decorations in a way that has never before been experienced. A crystal electrolier, by Defries, is now being suspended in the library, and it is proposed to light this with a mixture of ground and naked bulbs. Hitherto the Elphinstone-Vincent dynamo has been worked with six brushes. Future machines are to be worked with two, and these two by preference the pair at the top side of the commutator. The adjacent pairs of brushes are attached, but held off the commutator. In case of any trifling accident to the working brushes, one or both of them can be let down and the faulty brush removed without stopping the machine or causing any disturbance. Lord Elphinstone and Mr. Vincent find that their present size of commutator is amply large enough for the change, and that machines already built can have the arrangement of their brushes altered at a merely nominal cost. The advantages are that the workman has only two brushes to look after instead of six, that he has a pair in reserve, if needed, and, beyond this, the current in the external circuit is increased.

SECONDARY BATTERIES.*

On the evening of the 7th inst. Mr. C. T. Kingzett read a paper on the above-mentioned subject before the Society of Chemical Industry. After describing the many varied attempts which have been made during recent years to effect the economic storage of energy by means of electro-chemical processes, and incidentally pointing out their shortcomings, the author gave a general account of his own investigations, and the inventions to which they have led. These inventions are designed to obviate certain well-understood difficulties attending the so-called accumulators previously known to the public. For instance, the Faure-Sellon-Volckmar batteries are expensive, and exceedingly heavy; they suffer much loss by local action, and the formation of sulphate of lead which takes place during discharge at both elements causes loss of current energy in the charging process. Not only so, but the oxygen bearing plate or support is gradually, and, under certain circumstances, rapidly, destroyed by the ozonised oxygen set free thereat. Two supports made of metallic lead (or of lead alloyed with antimony) coated with red lead, and immersed in dilute sulphuric acid, constitute at the onset two primary batteries; that is to say, the minium oxidises the metal, and this action results immediately in the production of monoxide of lead, which subsequently is resolved into sulphate of lead by the action of the acid. Moreover, when such a combination is charged forthwith, the process results in an increase of the amount of peroxide of leads present at the one pole, and the formation of reduced lead at the other pole. At the negative pole, then, the conditions under which local action occurs are intensified; so are they, also, at the positive electrode (unless the whole of the minium be reduced), because, of course, reduced lead enters into reaction with minium much more readily than does the metal forming the support itself. Mr. Kingzett obviates all the difficulty at the positive pole by coating it with litharge instead of red lead, which, or the peroxide of lead, he still employs at the other terminal. A recently prepared paste of litharge and dilute sulphuric acid readily sets and hardens upon the supports, and such a mixture is much more easily reduced to the metallic state than is red lead, while the process requires also less hydrogen to effect it; that is to say, less electrolysis, and, therefore, a smaller expenditure of current energy. A mixture of red lead and acid sets or hardens almost as readily, and with this the oxygen-bearing support may be coated. Professor Frankland has, since the first patent was granted to Mr. Kingzett, patented the use of mixtures of oxides of lead and acids which form therewith insoluble salts, for placing in contact with the supports of secondary batteries without the use of any retaining material, but it will be seen that Mr. Kingzett claims originality in this particular, and also priority. He also claims the use of the two distinct compounds of lead, one at each of the respective supports.

He has also succeeded in effecting further new combinations, of which the following description may be taken in illustration:—Ordinary iron is employed to form both supports or electrodes, and they are prepared with the compounds of lead as already described, using for the electrolyte a bath of caustic soda or potash, or some neutral salt of an alkaline metal. Iron is, of course, much cheaper and much lighter than lead, and the reduction at the hydrogen-bearing plate takes place perfectly under the conditions of operating, the whole of the litharge being converted, so to speak, into metallic lead. The iron support used at the other pole is first coated either with magnetic oxide of iron, or with lead or otherwise, with the purpose of avoiding the attack upon this support by the oxygen, which would otherwise cause its gradual oxidation. Mr. Kingzett coats his negative plate of iron, for instance, with a dense and substantial thickness of lead by placing thereat the mixture of litharge and making it in the first place a hydrogen-bearing plate. When the reduction is complete, the support is ready for use as a oxygen-bearing plate, the attack of the oxygen being confined to the lead which is placed upon the support of iron. This metallic lead is in the fittest state for oxidisation, unlike the arborescent metal prepared by various expensive chemical processes, and unlike also the too spongy metal obtained by the electrolysis of an alkaline ley containing litharge dissolved in solution. The litharge being solid and dense, and confined in a limited space, the metal which results from its reduction is also continuous, dense, and greedily combines with oxygen, to form peroxide of lead. For use in an electrolyte of dilute sulphuric acid, a negative pole made of metallic lead or carbon may be similarly prepared with a coating of the reduced metal as just described.

Lastly, Mr. Kingzett constructs his supports or electrodes of a particular form, with the view of utilising the whole surface thereof, instead of a percentage only of the area, as in the per-

* The Paper of which this is an abstract will be published *in extenso* in the *Journal of the Society of Chemical Industry*.

Digitized by Google

forated plates of the Sellon-Volckmar type. The general form of Kingzett's electrodes is that presented by a brush, and the projections corresponding to the bristles are made solid or hollow, and perforated if desired.

In illustration, it may be mentioned that Mr. Kingzett exhibited two small supports, made as follows:—A sheet of ordinary iron is drilled at periodic intervals, and into the openings are screwed perforated gas tubes of any desired bore cut to any desired length; to secure perfect continuity and conductivity the tubes are soldered at the back of the base plate. Or the whole apparatus may be cast in this form, and may be made either of lead or of iron, according to whether an acid, or neutral or alkaline, electrolyte is to be employed. The compounds of lead which are used, as previously described, may be placed inside (only) the perforated tubes, or both inside and outside, and also upon the surfaces of the base plate, in which latter case the entire surface of the electrodes is covered with active material. Above all, this arrangement permits of the intimate flow of the electrolyte in contact with all parts of the secondary batteries, and obviates the employment of any excess of the materials, since the distance between the tubes is subject to will, and so also is the diameter of the tubes, and from this it follows that the compounds of lead are entirely converted during the charging process into active materials, and a good proportion of the charge put into the batteries can be obtained therefrom, while obviously local action is avoided.

Mr. Kingzett hopes shortly to make arrangements for the supply of accumulators constructed under his patents.

THE TRANSMISSION OF POWER BY MEANS OF ELECTRICITY.

Some further experiments were made on the 4th of March with M. Marcel Deprez's machines at the workshops of the Northern (of France) Railway, near Paris, by a special committee appointed by the Academy of Sciences. The arrangement of the machines, the circuit, measuring apparatus, and connections were identical with those employed on the occasion of the previous experiments made on the 18th of February, and reported on by M. Tresca. A translation of this report will be found in our issue of the 7th April, and an illustration of the mode of connecting up the machines in our issue of the 31st March, p. 477, in which we also gave a translation of that portion of M. Tresca's report relating to the first series of experiments carried out on the 11th of February. The account of the further experiments of the 4th of March was presented to the Academy by M. Cornu in the name of the committee. It is a somewhat lengthy document, and therefore we do not propose to reproduce it in full. It commences by a brief allusion to the researches of Faraday, Gauss, Weber, and Siemens, describing the discovery of the former as the germ of all subsequent progress. Having repeated M. Tresca's description of the machines and the arrangement of the apparatus (see *The Electrician* for March 31), the report gives the following table of dynamometrical measurements obtained by the committee. These were under the charge of M. Tresca, M. Cornu being responsible for the electrical measurements:—

TABLE I.—*Dynamometrical Measurements* (taken with General Morin's dynamometer).

No. of experiment.	Dynamometer. No. of revolutions per minute. v	Dynamometer. Mean ordinate of the diagram. y	Generator. No. of revolutions per minute. N	Receiver. No. of revolutions per minute. n	Receiver. Weight on the brake.	Remarks.
		mm.			kg.	
I.	59	12·68	378	104	5	
II.	57	13·18	370	88	5

VIII.	1·50	11·70	10·20	0·60	— 9·55	

The report then goes at considerable length into the coefficients of reduction adopted for the dynamometrical and electrical measurements, and experiments made to test the accuracy of the dynamometer and galvanometers. The reduction of the observations made led to the results given in Table III.

TABLE III.

Dynamometrical Results.

No. of the experiment.	No. of revolutions per minute. Generator N.	No. of revolutions per minute. Receiver n.	Mechanical work. Furnished by the pulley of the dynamometer T.	Furnished at the generator T m.	Received at the brake on the receiver T u.	Transmitted per revolution of the generator.	Dynamometrical return. 			h.-p.	h.-p.	h.-p.	h.-p.		
I.	378	104	3·838	3·296	0·578	0·00 153	0·151	0·176
II.	370	88	3·854	3·331	0·489	105	0·127	0·147
V.	850	602	9·771	7·665	3·344	393	0·342	0·435
VI.	923	709	10·556	8·259	3·939	427	0·372	0·477
VII.	850	643	9·514	7·408	3·572	420	0·375	0·482
VIII.	1024	799	12·267	9·751	4·439	433	0·362	0·456

From this table it appears that the work absorbed by the generator and transmitted to the receiver increased with the speed of the generator. The grand fact that is established is that nearly 4½ horse-power has been transmitted through a resistance of 160 ohms, representing a double telegraph line of 8·5 kilometres long (9295·60 yards). The gross return will be represented by 37½ per cent. of the work expended, if we take into account the losses which every motor sustains when working. But if we neglect the mechanical motor altogether, and deal exclusively with the result obtained by successive transformations of energy, we may call the dynamometrical return 48 per cent.

The figures in Table III., combined with those given in M. Tresca's previous report, seem to indicate that, if the quantity of work transmitted increases with the speed of the machines, the return attains its maximum when the speed of the generator reaches about 850 revolutions. It would seem that the generator had not reached its maximum power, and that a quicker speed would permit of a much larger amount of work being transmitted. Experiment confirms this view in another way; with such high speed for the generator, the receiver which was em-

Digitized by Google

ployed, and which was an old Gramme machine modified, appeared to have reached its maximum power. Its collectors were covered with continuous and extremely brilliant sparks, and often quite a circle of fire would suddenly surround the whole periphery of the shaft. The machine was saturated, and would have been in danger of destruction if a larger amount of electrical work had been laid on it. The generator, on the other hand, worked in a far more regular manner, and the sparks at the collectors were slight. It is very probable, therefore, as has been suggested by M. Deprez, that far better effects would have been obtained if the receiver and generator had been identical.*

The electrical results are given in

TABLE IV.

Electrical Results.

No of the experiment. VI.	923	709	2·52	2086	1685	159	2229	1468	0·658
VII.	850	643	2·57	1937	1479	179	2083	1258	0·604
VIII. ...	1029	799	2·50	2338	1994	138	2480	1779	0·717
					Average	159·6			

The first result demonstrated by this table is that the resistance offered by the telegraph line during the transmission, that is with a current of about 2·5 amperes, remained nearly steady at 160 ohms, the resistance which it was found to offer with a current of ·01 ampere during the preliminary tests. The average of 159·6 (see table) coincides very nearly with 160. The divergence of the figures is accounted for by the variations in the speed of the machines, and also by the impossibility of making the measurements of U, u, and C absolutely simultaneous. This identity between the effective and measured resistances of the line is very important, showing as it does the agreement of theory with practice, when the phenomena of the transformation of energy in a circuit are analysed. It shows that the energy necessary to overcome the resistance of 160 ohms is practically equal to the theoretical value found for it. This energy, expressed in kilogrammetres per second, is equal to $\frac{\rho C^2}{g}$, and, in horse-power, $\frac{\rho C^2}{75\,g}$. As the current remained constant, or nearly so, at 2·5 amperes, the loss of mechanical work is equal, for all the experiments, to about

$$\frac{160 \times \overline{2 \cdot 5}^2}{75 \times 9 \cdot 81} = 1 \cdot 358 \text{ horse-power.}$$

We know that this amount of energy is diffused in the shape of heat.

Another result predicted by theory is the ratio of the electromotive force to the speed, the current being constant; if, in fact, we calculate the quotients

$$\frac{E}{N} \text{ and } \frac{e}{n},$$

we find

Experiments	I.	II.	VI.	VII.	VIII.
Generator $\frac{E}{N}$.	2·26	2·40	2·41	2·45	2·42
Receiver $\frac{e}{n}$.	1·12	1·57	2·07	1·96	2·23.

The ratio for the generator is very satisfactory, as it is also for the receiver in those cases where the speed n was accurately measured.

The last column of Table IV. gives the ratio of the E.M.F.'s $\frac{e}{E}$ developed in each machine. It has long been known that this ratio represents the dynamometrical return when the induction phenomena which always accompany the production of the principal current in dynamo machines are neglected. Thus we have, according to the well-known theory of the conservation of energy,

$$E\,C = T_m,\; e\,C = T_u,$$

calling T_m the work actually given to the generator and T_u the work received at the receiver. From which we conclude that

$$\frac{e}{E} = \frac{T_u}{T_m},$$

which demonstrates the identity of the two returns.

It will be remarked that E and e are united by Ohm's law, so that we may write, calling R and r the internal resistances of the two machines,

$$(R + r + \rho)\,C = E - e,$$

that is to say,

$$\rho\,C = (E - RC) - (e + r\,C) = U - u,$$

a relation exactly verified above.

Experiment shows that the electrical return is far higher than the dynamometrical return, a grave objection to the electrical theory of the transmission of power. Happily the origin of this difference is readily found. As we have seen that this difference does not originate in the line of transmission, it can only be met with at the localities where the transformation of electrical energy into mechanical energy, and *vice versâ*, takes place. Now, experiment gives the value of the electrical energy in each machine; we can, therefore, compare it directly with the dynamometrical figures T_m and T_u. We know that electrical energy is expressed in horse-power by dividing the products E C and e C by 75 g ($g = 9 \cdot 81$). By this means we can readily form the following table:—

TABLE V.

No. of the experiment.	Electrical energy developed in. The generator $\frac{E\,C}{75\,g}$.	Electrical energy developed in. The receiver $\frac{e\,C}{75\,g}$.	Mechanical work. Given to the generator T_m.	Mechanical work. Received at the receiver T_u.	Practical coefficient of transformation. For the generator.	Practical coefficient of transformation. For the receiver.
	h.-p.	h.-p.	h.-p.	h.-p.	H.	h.
I.	2·668	0·362	3·296	0·578	0·809	1·596 ?
II.	2·923	0·454	3·331	0·489	0·877	1·077 ?
VI.	7·336	4·831	8·259	3·939	0·888	0·815
VII.	6·991	4·222	7·408	3·572	0·944	0·846
VIII.	8·097	5·809	9·731	4·439	0·832	0·764
			Average		0·870	0·806

It will be seen that for each of the machines the energy developed is inferior to the energy expended, of which it should theoretically be the equivalent. In the two cases, although the transformations are of inverse character, there is a loss of useful energy, so that if we call the practical coefficient of transformation of the generator H, and that of the receiver h, corresponding to their speeds, we must substitute for the equations of the conservation of energy the following:

$$E\,C = H\,T_m,\; h.e\,C = T_u,$$

so that the dynamometrical return becomes

$$\frac{T_u}{T_m} = H\,h\,\frac{e}{E}.$$

We thus see why the dynamometrical return is always less than the electrical return. The coefficients h and H evidently depend upon the construction of the machines and their speeds. The figures given in this report and those obtained on the 18th February induce the belief that this product, approaching unity for slow speeds, diminishes rapidly with high speed.

The report then discusses the relative efficiency of the two machines used, and the means adopted by M. Deprez to improve that efficiency for the special object in view, viz., the transmission of power. It concludes with the following words:—

"The committee is not qualified to judge of the economic value and the industrial future of the results obtained; but after a most careful examination of the *apparata* and principles employed, it does not hesitate to proclaim the importance of the facts that have been demonstrated. In consequence, it proposes that the academy should congratulate M. Marcel Deprez on the important progress he has made towards the solution of the very interesting problem of the electrical transmission of power, and encourage him to pursue his labours, and continue, as he has done up to the present, to place the resources of an ingenious mind at the service of the principles of electrical science."

* When a trial was made with this generator with the view of determining its characteristic at 740 revolutions per minute, the current in a short circuit (250 ohms), according to M. Deprez's measurements, reached 9·80 amperes, which corresponds to an expenditure of 30 horse-power; it might, at the same time, it appears, have accidentally absorbed as much as 50 horse-power.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

(CONTINUED FROM PAGE 22.)

The Starry Galileo had his say on the same subject, and, as we may expect, said it well: "You remind me," says he, "of one who offered to sell me a secret art, by which, through the attraction of a certain magnetic needle, it would be possible to converse across a space of two or three thousand miles. And I said to him that I would willingly become the purchaser, provided only that I might first make a trial of the art, and that it would be sufficient for the purpose if I were to place myself in one corner of the room and he in the other. He replied that, in so short a distance, the action would be scarcely discernible; so I dismissed the fellow, and said that it was not convenient for me just then to travel into Egypt, or Muscovy, for the purpose of trying the experiment, but that if he chose to go there himself, I would remain in Venice and attend to the rest"! ("Dialogus de Systemate Mundi," 1632, p. 88.†)

Cardinal Richelieu's system of espionage was so perfect that he was regarded (and feared) by his contemporaries as a dabbler in "diabolical magic." He was supposed to have possessed either a magic mirror, in which he could see all that went on in the world, or the equally magic magnetic telegraph. *A propos* of this, we find the following passage in the "Letters writ by a Turkish Spy," a work which has been attributed by the elder Disraeli to John Paul Marana:—"This Cardinal said, on another time, that he kept a great many courtiers, yet he could well enough spare them; that he knew what passed in remote places as soon as what was done near him. He once affirmed he knew in less than two hours that the King of England had signed the warrant for the execution of ———. If this particular be true, this Minister must be more than a man. Those who are his most devoted creatures affirm he has in a private place in his closet a certain mathematical figure, in the circumference of which are written all the letters of the alphabet, armed with a dart, which marks the letters, which are also marked by their correspondents, and it appears that this dart ripens by the sympathy of a stone, which those who give and receive his advice keep always at hand, which hath been separated from another which the Cardinal has always by him; and it is affirmed that with such an instrument he gives and receives immediately advices." (13th letter, dated Paris 1639, Vol. 1.)

The learned Physician, Sir Thomas Browne, has some cautiously worded sentences on the mythical telegraph, which are worth quoting. "There is," he says, "another conceit of better notice, and whispered thorow the world with some attention; credulous and vulgar auditors readily believing it, and more judicious and distinctive heads not altogether rejecting it. The conceit is excellent, and, if the effect would follow, somewhat divine; whereby we might communicate like spirits, and confer on earth with Menippus in the moon. And this is pretended from the sympathy of two needles, touched with the same loadstone, and placed in the center of two abecedary circles, or rings, with letters described round about them, one friend keeping one, and another the other, and agreeing upon an hour wherein they will communicate. For then, saith tradition, at what distance of place soever, when one needle shall be removed unto any letter, the other, by a wonderful sympathy, will move unto the same. But herein I confess my experience can find no truth, for having expresly framed two circles of wood, and, according to the number of the Latine letters, divided each into twenty-three parts, placing therein two stiles, or needles, composed of the same steel, touched with the same loadstone and at the same point. Of these two, whenever I removed the one, although but at the distance of but half a span, the other would stand like Hercules pillars, and, if the earth stand still, have surely no motion at all."—("Pseudodoxia Epidemica," Book II., chap. 3).

The "Scepsis Scientifica" of Joseph Glanvill, published in 1665, and which, by the way, secured his admission to the Royal Society, contains, perhaps, the most remarkable allusion to the prevailing telegraphic fancy. Glanvill, albeit very superstitious, was an ardent and keen-sighted philosopher, and held the most hopeful views as to the discoveries that would be made in aftertimes. In the following passages he clearly foretells, amongst other wonders, the discovery and extension of telegraphs:—

"Should those heroes go on as they have happily begun, they'll fill the world with wonders. And I doubt not but posterity will find many things that are now but rumours verified into practical realities. It may be some ages hence a voyage to the southern unknown tracts, yea, possibly the moon, will not be more strange than one to America. To them that come after us, it may be as ordinary to buy a pair of wings to fly into the remotest regions as now a pair of boots to ride a journey. *And to confer at the distance of the Indies by sympathetic conveyances may be as usual to future times as to us in a literary correspondence.*"—C. xix.

"That men should confer at very distant removes by an extemporary intercourse is a reputed impossibility, yet there are some hints in natural operations that give us probability that 'tis feasible, and may be compast without unwarrantable assistance from dæmoniack correspondence. That a couple of needles equally toucht by the same magnet being set in two dyals exactly proportion'd to each other, and circumscribed by the letters of the alphabet, may effect this magnale hath considerable authorities to avouch it. The manner of it is thus represented. Let the friends that would communicate take each a dyal; and having appointed a time for their sympathetic conference, let one move his impregnate needle to any letter in the alphabet, and its affected fellow will precisely respect the same. So that would I know what my friend would acquaint me with, 'tis but observing the letters that are pointed at by my needle, and in their order transcribing them from their sympathized index as its motion directs: and I may be assured that my friend described the same with his, and that the words on my paper are of his inditing. Now, though there will be some ill contrivance in a circumstance of this invention, in that the thus impregnate needles will not move to, but avert from each other (as ingenious Dr. Browne in his 'Pseudodoxia Epidemica' hath observed), yet this cannot prejudice the main design of this way of secret conveyance, since 'tis but reading counter to the magnetic informer, and noting the letter which is most distant in the abecedarian circle from that which the needle turns to, and the case is not alter'd. Now, though this desirable effect possibly may not yet answer the expectation of inquisitive experiment, *yet 'tis no despicable item, that by some other such way of magnetick efficiency it may hereafter with success be attempted*, when magical history shall be enlarged by riper inspections, and 'tis not unlikely but that present discoveries might be improved to the performance."—C. xxi.

At the end of this chapter we give a list of references, as complete as we could make it, which will be useful to those of our readers who may wish to pursue the subject. It will also be instructive from another point of view, for it illustrates, in a very complete way, what Professor Tyndall has so well called the "menial spirit" of the old philosophers.* Notwithstanding that some of the more enlightened authors endeavoured laboriously to disprove the story, it was, for the most part, blindly and unquestioningly repeated, by one writer after another—credulous and vulgar auditors, as Sir Thomas Browne says, readily believing it, and more judicious and distinctive heads not altogether rejecting it, amongst whom we are tempted to reckon the learned knight himself.

Of those who stoutly and, at an early period, combatted the story, Fathers Cabeus and Kircher deserve to be mentioned—the one for the excellence, and the other for the vehemence of his observations. Those of the former are particularly remarkable, as containing a hazy definition of the "lines of force" theory—a theory which Faraday has turned to such good account in his "Experimental Researches." Cabeus, as well as I can understand him, says, in his tenth chapter:—"The action by which compass needles are mutually disturbed is not brought about by sympathy, as some persons imagine, who consider sympathy to be a certain agreement, or conformity, between natures or bodies which may be established without any communication. Magnetic attractions and repulsions are physical actions which take place through the instrumentality of a certain quality, or condition, of the intervening space, and which extends from the influencing body to the influenced body. I cannot admit any other mode of action in magnetic phenomena; nor have I ever seen in the whole circle of the sciences any instance of sympathy or antipathy (at a distance). . . .

"That which is diffused as a medium (or, that quality, or condition, of the intervening space) is thin and subtle, and can only be seen in its effects; nor does it affect all bodies, only such as are either conformable with the influencing body, in which case the result is a perfecting change (or sympathy = attrac-

† It is curious that Kepler appears to have believed in the efficacy of the sympathetic telegraph. See Fournier's "Le Vieux Neuf," Paris 1857, Vol. I., page 200.

* "The seekers after natural knowledge had forsaken that fountain of living waters, the direct appeal to nature by observation and experiment, and had given themselves up to the remanipulation of the notions of their predecessors. It was a time when thought had become abject, and when the acceptance of mere authority led, as it always does in science, to intellectual death. Natural events, instead of being traced to physical, were referred to moral causes; while an exercise of the phantasy, almost as degrading as the spiritualism of the present day, took the place of scientific speculation."—Tyndall's address to the British Association at Belfast, 1874.

Digitized by Google

tion), or non-conformable, in which case the result is a corrupting change (or antipathy = repulsion). This quality is, I repeat, thin and subtle, and does not sensibly affect *all* intermediate (*i.e.*, neighbouring) bodies, although it may be disseminated through them. It only shows a sensibly good or bad effect according to the natures of the bodies opposed to one another.

"Bodies, therefore, are not moved by sympathy or antipathy, unless it be, as I have said, through the medium of certain essences (forces) which are uniformly diffused. When these reach a body that is suitable, they produce certain changes in it, but do not affect (sensibly) the intervening space, or neighbouring non-kindred bodies.—Thus the sense of smell is not perceived in the hand, nor the sense of hearing in the elbow, because, although these parts are equally immersed in the essences (or forces) they are not suitable or kindred in their natures to the odoriferous or acoustic vibrations."* ("Philosophia Magnetica," &c., chap. 10.)

Kircher scouts the notion in no measured terms; after soundly rating the propagators of the fable on their invention of the terms *chadid*, *almagrito*, *theamedes*, *almaslargont*, and *calamitro*—vile jargon, which, he says, was coined in the devil's kitchen—he thus delivers himself:—"I do not recollect to have ever met anything more stupid and silly than this idiotic conception, in the enunciation of which I find as many lies and impositions as there are words, and a crass ignorance of magnetic phenomena withal. In their craving after something wonderful and unknown they manufactured a secret by means of barbarous, and high-sounding words, and by imitating the forms of recondite science, with the result that even they themselves could not understand their own words" ("Magnes, sive de arte magnetica," Book II., Part IV., Chapter 5).

ELECTRICITY AS A MOTIVE POWER.†

BY PROFESSOR GEORGE FORBES.

(CONTINUED FROM PAGE 24.)

I have said that, to produce a good mechanical effect with a dynamo used as a motor, it is necessary to drive it at a high speed. This speed is generally too great for ordinary mechanical applications. For example, we do not require the wheels of a tramcar to turn at anything like a speed of 800 turns a minute. In such applications, then, it becomes necessary to reduce the speed by suitable gearing. Thus, in the electrical tramcars which have been constructed hitherto, belting has been used, or some equivalent. This is an awkward expedient, and one which, in practice, is found to give much trouble. I am inclined to think that, in making an electrical railway, it would be preferable to make the wheels of small diameter, and attached directly to the axle of the motor. This seems to be by far the best plan in the present state of affairs. It may be that a motor will be found which will work economically at a lower speed; but with those which are now at our disposal it would be best to work with very small wheels.

We now come to consider, directly, the transmission of energy to a distance. There are two separate kinds of application. One is to fixed motors, the other to locomotives. Let us begin with the stationary motors. There is no doubt that if electricity be capable of transferring the water-power of rivers to the centres of mechanical industry, if it be capable of introducing economy by burning coal at the pit mouth, or the bottom of the pit shaft, then we have a vast engineering industry ready to open out.

It is not until we have sat down and worked out from experimental data the cost of installation and maintenance, that we can pronounce an opinion on the merits of such schemes. When we want to send a large quantity of energy to a distance, through a thin wire, we must use the highest electromotive force which we consider safe, and the most powerful current which the conductor will bear without either fusing or injuring its supports by heating, and then we have no means of increasing the amount of energy which we can send, except by increasing the size of our conductors. Unfortunately, when we double the weight of our conductors we do not double the current which we can pass through them. Hence there must necessarily be a limit to the quantity of energy which can be sent along a single line, which limit is reached when the cost of the conductor becomes too great. When a limit is thus attained, the only way of increasing the transmission of energy economically is by increasing the number of systems of conductors, or else by introducing means of cooling the conductors. These are the considerations which have guided M. Deprez in his experiments. But Sir William Thomson has shown that the loss of horse-power in heating the conductor more than compensates for the expense of thicker conductors. For economy, we ought to have the value of horse-power thus worked equal to the value of interest and depreciation of conductors.

In such an installation we require to consider not only the quantity of power which can be transmitted, but also the efficiency of the arrangement. Now, the efficiency varies with the quantity of power which is transmitted. If we transmit very little energy we get a high efficiency, nearly = 1; if we transmit the maximum amount of energy possible the efficiency is ½. In fact, the work done by the motor is proportional to the efficiency minus the square of the efficiency:

where $w = 4\,M\,(e - e^2)$,
M = the maximum work possible,
e = the efficiency,
w = the actual work returned,

and consequently, when the efficiency is nearly equal to unity, the work done is zero. It is found in practice to be preferable to get nearly the maximum work out of a machine, rather than to increase the size and cost of the machines, in order to get a certain amount of work from the apparatus.

Of course it is only after long experience that we shall know what is the maximum power which we can send along a wire, and what limits must be put to the electromotive force which we use. M. Marcel Deprez has spent much time and labour on making practical tests of this nature. One of these formed a chief attraction at the Munich Exhibition last year, where he used an iron telegraph wire, 4mm. diameter (or a sixth of an inch), and transmitted ½ horse-power to a distance of 35½ miles. He has since been carrying on experiments of the same kind at Paris. The results have lately been published, and I shall return to them.

One of the chief things which I proposed to myself when I was asked to read a paper here was to give some account of the experiments which I saw at Munich. I was very much struck indeed with the transport of energy by Mr. Schuckert, of Nürnberg, not that there was any new principle involved, but I had never before seen so much as 5 or 6 horse-power conveyed by a thin wire so far as three and a-half miles. The power was derived from a turbine, at Hirschau, beyond the English gardens. These turbines are employed on a locomotive factory, no steam being used in any of the shops. They have thus 260 horse-power at their disposal. The machine at Hirschau was of a larger size than the motor in the exhibition. This is a point on which Mr. Schuckert has made careful experiments. This machine, which was driven by the turbine, worked a number of agricultural machines during the day, and served to light thirteen Pilsen lamps at night, both being in the exhibition building. The turbine being a very large one, and revolving slowly, transmitted its power to the dynamo by belts. A turbine is a very convenient motor for a dynamo, for it happens that when we are using a dynamo requiring the whole power of the turbine the proper speed for each is nearly the same, so that the dynamo may be attached directly to the shaft of the turbine, which is, of course, a very great convenience and a saving of power. In my experiments, in conjunction with Dr. Young, on the velocity of light, at Wemyss Bay, I made use of such an arrangement for producing the electric light. A small Siemens machine was attached directly to a Thomson's vortex turbine with horizontal shaft. The water was led from a distance of nearly a mile. The convenience of being able to start the electric light by merely turning a handle was very great indeed, and I can recommend this arrangement to any one who has water-power at his disposal.

But to return to the Hirschau installation. A pair of No. 7 copper wires conveyed the current, one-eighth of the E.M.F. being wasted in heating the wire. This installation, taken as a whole, was much to be admired. I do not say that there was anything new or much information to be gained from it, but it showed to every one visiting the exhibition a good working, practical installation. Mr. Schuckert has been good enough to give me the results he has obtained from two experiments with different sets of machines. All the four machines with which these experiments were made are constructed for generating a current of eight amperes. In one experiment the generator was constructed for fifty-five incandescent lamps, with a motor constructed for thirty-three lamps (the lamps being in compound

* "A brief letter from a young Oxonian to one of his late fellow-pupils upon the subject of Magnetism," London, 1697, contains, at page 10, a "draught" which illustrates very well the arrangement of magnetic lines of force, and which differs but little from the graphic representations of the present day. The curious little pamphlet is one of many gems in Mr. Latimer Clark's library.

† Paper read before the Society of Arts on Wednesday, May 2, 1883.

Digitized by Google

parallel). In the other he used as generator a machine for about 150 lamps, with a motor made for eighty-eight lamps. The particulars of the machines are given in the following table, from which we see that in each case 36 per cent. of the energy put into the generator was reproduced as work done by the motor :—

	First Experiment.	Second Experiment.
Type of Generator	TL 3	TL 5
Type of motor	TL 2	TL 4
Difference of potential—		
(1) At terminals of generator	300	700
(2) ,, ,, motor	230	600
Resistance of leaders	6 ohms.	12 ohms.
H.-P. spent on generator	4·4	12·8
H.-P. given by motor	2·5	5·8
Efficiency (per cent.)	36	36

I give you these figures, not because they show any wonderful performance, but because it is desirable to have as many facts as possible when any new idea is being developed.

You see that, in these experiments, the aim has not been so much to get a high efficiency as to get a high amount of power developed. This is what ought always to be done, while the machines form the chief item of cost.

Let us now speak of the experiments of M. Marcel Deprez. In 1881, M. Deprez published the theory of transmission of energy to a distance, by means of a thin wire. It is a theoretical fact that, if you get a certain return by using a given generator and a given receiver, and with a certain length of wire between the two, you can double the distance with the same results as to power, using the same thickness of wire, if you construct a new generator and a new receiver, wound with smaller wire, so as to have double the resistance of wire wound, the other dimensions of the machine being unchanged. This had been known before, and the theory had been fully worked out by Frölich and others. But Deprez had the credit of working out numerical examples, and of afterwards putting the theory to the test of experiment. In his first paper, he started with some experiments made at Chatham, in which two Gramme machines were used, one as generator, the other as receiver; when through a line-resistance equal to that of either machine, a return of 50 per cent. was obtained. He then showed that theoretically a similar pair of machines could be constructed so as to transmit 50 per cent. of the energy to a distance of 100 kilometres, an ordinary telegraph wire being used, 4 mm. thick, giving a resistance of 9 ohms to the kilometre. He also stated that 12 horse-power being used by the generator, 6 horse-power would be delivered by the receiver. I do not consider that the theory in this paper was quite clear, but the main point was proved.

After the the publication of this paper, the Munich Exhibition was a thing of the immediate future, and M. Deprez was invited to make his experiment with a distance of sixty kilometres. The resistance of a telegraph wire of this length, using the earth for the return, was 475 ohms. Consequently two machines were made of the normal type, like an "A" Gramme, each of 453 ohms resistance. These machines developed very high electromotive forces (about 2,000 volts), and when they were installed it was naturally discovered to be impossible to use the earth as a return. Consequently another wire was used, increasing the resistance to 950 ohms. This militated against the complete success of the experiment, and I think it is unfortunate that, in their desire to assert the success of the experiments, the friends of M. Deprez withheld this fact from the public, and so led many people to believe that the theory was inexact. As a matter of fact, owing to the great resistance of the line, 60 per cent. of the total electric effect was used up in heating the circuit, instead of 40 per cent., as had been calculated. In order, then, to get a satisfactory return, it was necessary to allow the receiver to do very little work. Thus, in the trial made by the committee of experiments before the machine broke down, only 0·433 of a horse-power was utilised at Munich, and there was a return of 39 per cent. of the power put into the machine at the distant station of Miesbach.

These experiments were of a very high degree of interest, and M. Deprez deserves the thanks of scientific men for the zeal he showed in carrying them out. Let us see, now, whether an economy would thus be introduced by burning coal at the pit mouth, and transmitting power as in the Miesbach experiment. Allowing 3lb. of coal per horse-power per hour, if we work twenty-four hours a day for 300 days in the year, we have almost exactly 10 tons of coal per horse-power per annum. Suppose the coal costs 5s. a ton at the pit mouth, and a ½d. per ton for transport over the kilometre, it follows that the cost of furnishing 0·433 of a horse-power at Munich by transport of coal would be the cost of 4·33 tons of coal, and their transport over 60 kilometres, amounting to £1 11s. 6d. The cost of coals to work the machine at Miesbach, with a duty or efficiency of 39 per cent., would be £2 19s. Let us assume the machines to cost £100 together, then, neglecting the cost of the telegraph wire, and allowing 15 per cent. for interest and depreciation of the machines, neglecting also the extra cost of the larger steam engine required at Miesbach, we have an annual expense of £17 19s. for the power delivered electrically at Munich against £1 11s. 6d. for the same power delivered by the transport of coal. Even if the machines cost nothing there would be a loss; if the power cost nothing there would also be a loss. It is folly to use machines costing so much only to produce ½ horse-power.

I have no doubt that M. Deprez could have got more than a ½ horse-power at Munich, but had he attempted this it would have been at a cost of efficiency. It cannot be too constantly borne in mind that, in electro-mechanics, you can increase your efficiency almost up to unity, but at a sacrifice to the total amount of work transmitted. But it must also be constantly remembered that you increase your total work up to a certain maximum, but at the cost of efficiency. The maximum efficiency is obtained when the load is so great that the motor is only just able to turn round. The efficiency is greatest when the load is so light that the motor turns nearly as quickly as the generator. I repeat that an erroneous idea has been promulgated that we ought always to run motors at a speed approaching to this condition of maximum efficiency. But if this be done, the return of work is insufficient to pay for interest and depreciation on the plant required.

The very important experiment of M. Deprez, at Munich, is able to give us much information for future use. Among other facts, we learn that with machines of the type described by him, 2,000 volts is too high an electromotive force to employ. The reason is that it is impossible to prevent the contact of the brushes from being sometimes accidentally broken. In such a case it was found that the electromotive force developed by the extra current is sufficient to ruin the insulation.

Another matter deserving of attention is the relative size of the generator and motor. M. Deprez employed two machines of equal size. This slightly simplifies the theory, but it is certainly not the most advantageous arrangement, and we are much in want of accurate measurements on this head.

From what has been said, it is clear that the Deprez experiment at Munich was, commercially, a failure. You might, at first sight, think that if a thoroughly scientific experiment like this was a commercial failure, there are no cases in which it would be a commercial success. This is by no means the case. Since the time of the Munich Exhibition, M. Deprez has been occupied with experiments of a far more practical nature, with a line of 160 ohms resistance. In the latest experiments, where the effects of friction were deducted, a return of 47½ per cent. was obtained, and 4·4 horse-power of work was actually given off by the motor. Judging from the Hirschau experiment I should say that if a fall of water be used as the motive power, we can install a turbine and dynamos, which shall transmit 6 horse-power through a resistance of 12 ohms, at a cost of £200, neglecting the unknown cost of the conductor. If this power were in used a place where coal costs 20s. per ton, the cost of fuel for 6 horse-power would be about £60 per annum. The interest and depreciation on the boiler and steam engine would be about £30 per annum, making in all £90 per annum, exclusive of wages. Electrically transmitted, the interest on plant at 15 per cent. would be £30 per annum, exclusive of wages. This difference of £60 per annum, after deducting from it the interest and depreciation of the conductor, is so enormous that it is easy to see what a large saving would be effected in any installation where there is a large consumption of power. There are many factories where it is essential to use a high-priced coal, but if the power could be conveyed electrically from a distance of a few miles an immense saving would be effected by employing a cheaper kind of coal. When water power is used it often happens that we can convey the cables along the bed of the river. This preserves the insulation and keeps the conductor cool, so preventing the usual increase of resistance by heating.

In some towns, and notably in Sheffield, the whole of the water supplying the town comes from reservoirs at a very great height. The very large quantity of energy of this water is at present absolutely wasted; and although coals are not dear in Sheffield, and manufacturers are permitted to burn the most smoky kind of coal in the centre of the town, yet the employment of this waste water-power would add very considerably to the commercial prosperity of the town, and the water would be injured in quality no more by passing through turbines, than by passing through the present pipes. If this power were distributed electrically, the benefit to the community would be great indeed.

At the site of the Severn Tunnel there is a width of river of two and a-half miles, where the average rise of tide is thirty feet. If the average rate of flow across this section were one

Digitized by Google

mile per hour, we could utilise 100,000 horse-power, and the market value of that power is something like £1,000,000 per annum, which is now allowed to be wasted. It is worthy of the most serious consideration whether it would not be worth while to erect the enormous engineering works which would be required to utilise this wasted energy, or rather a portion of it. Assuming the interest and depreciation on the turbines and dynamos to be at the rate of £2 per annum per horse-power (and it would be far less than this for a large installation), it is easy to see that a time will come when this source of wealth will not be allowed to be wasted.

I wish to draw special attention to this point, because I have frequently heard people say, with regard to the utilisation of the tides, "Oh, that is out of the question; Sir William Thomson has proved that the area required to produce 100 horse-power is so great that it would be more worth while to reclaim the land and cultivate it." Now, Sir William never said such a thing. It is true that at the York meeting of the British Association he showed what area would require to be enclosed in order to produce 100 horse-power on the supposition that there was a rise of tide of only 6ft. 7in. (two metres). And he made use of the following expression :—"Thus we are led up to the interesting economical question, whether is forty acres . . . . or 100 horse-power more valuable." But in the case I am considering, the height of the tide is six times that contemplated by Sir William, and the question is rather "whether is forty acres or 600 horse-power more valuable." The estimate I made above, as to the value of a horse-power, agrees with Sir William's; and the value of 600 horse-power is £6,000 per annum. I confidently state that the reclaimed land on the Severn would not be worth £150 per acre per annum. I have taken the site of the Severn Tunnel as an example, but there are many other places available, and I have little doubt that the industrial population at Bristol will soon realise the wealth of power at their doors.

Some people in this country are timid about the introduction of large turbines. This, I need hardly say, is a gross prejudice. At Connecticut, Massachusetts, 30,000 horse-power is derived from the river by turbines. At Narva, near St. Petersburg, one firm uses 12,000 horse-power, and the size of the turbines used, which were made at Augsberg, was limited only by the size of the tunnels on the railways by which they had to be conveyed. At Munich I saw 260 horse-power rendered available by means of turbines with a fall of less than two metres. In the remote valleys of Italy there are several installations of incandescent electric lighting by means of turbines driving the machines of Messrs. Crompton. In Scotland, too, we have powerful turbines. Mr. Pirie, the paper maker, has introduced, near Aberdeen, turbines working up to nearly 1,000 horse-power. At Greenwich large overshot wheels are employed. The Shaws Water Worsted Company are now replacing one of these 200 horse-power by a turbine. In Lancashire water-power is also extensively used. At Valserine, on the Rhône, a canal has been cut through the rock, a third of a mile in length, thus giving a fall of about 12 metres and many hundred horse-power, using Jonval turbines. It is proposed to use the falls at Bellegarde, near Geneva, in the same way. The Manville Cotton Company, at Albion, R.I., use turbines, with a fall of 5·4 metres, which takes the place of a steam engine of 800 horse-power, and economy is materially gained, although during the five months of the dry season they are obliged to use steam. At the Pittsburg Mill, Minneapolis, there is a Victor turbine, working up to 1,400 horse-power, and another is being added of the same dimensions. These are only a few examples to show how thoroughly practical, economical, and convenient the use of turbines has become. We can, with them, calculate on utilising 75 per cent. of the theoretical power of the head of water. They can be controlled with the utmost ease. Their cost is very small compared with water-wheels, and they can be geared directly on to the shafts of dynamos. As an example of their adaptability to the purposes of the electrician, I may mention the performance of a Fourneyron turbine established at St. Blaise in the Black Forest, which utilises a fall of 108 metres, turns at a speed of 2,300 revolutions a minute, and gives off 60 horse-power.

The engineering works which would be required on the Severn would be very simple, though on a large scale, and the action could be made quite continuous, independently of the state of the tide, and without any necessity of using accumulators.

(TO BE CONTINUED.)

A CYCLONE.—A cyclone which swept through the States of Illinois and Wisconsin, on Friday and Saturday last, is described as "an enormous funnel, five hundred feet high, around the top of which the lightning played."

ELECTRIC LIGHTING OF LEEDS.

Particulars to accompany plans relating to the proposed lighting by electricity of portions of the municipal buildings at Leeds for the Corporation.

The Electric Lighting Committee of the Corporation of Leeds are prepared to receive tenders for lighting by electricity the following places, namely :—In the Town Hall : (1) The Victoria Hall. (2) The vestibule. In the New Municipal Buildings : (3) The vestibule. (4) The general pay office. (5) The gas and water clerk's office. (6) The general reading room—library division. (7) The lending library. (8) The reference library—lower level. (9) The reference library—upper level. Outside lighting : (10) In front of the Town Hall.—Victoria-square : (11) In Calverley-street.

The committee desire it to be distinctly understood by persons who may be prepared to tender that the positions indicated on the plans for the incandescent lamps and pendants, and the number of lamps mentioned as being considered sufficient to efficiently light the places named, are suggestions only on the part of the committee, and are given with a view to the tenders being prepared upon a common basis. Persons tendering are at liberty to suggest any probable improvement, either as regards the proposed position or number of the lamps, or with reference generally to the proposed scheme of lighting. If any departure is made from the character of the installation, as herein suggested, the tenders should be in an alternative form, namely :—1st, To cover the cost of the lighting as suggested by the committee ; and, 2nd, to cover the cost of any alternative scheme of lighting proposed in the tender.

PARTICULARS.

1. THE VICTORIA HALL.—The Victoria Hall in the Town Hall is 130ft. long, 71ft. wide, and 72ft. 3in. high. It is at present lighted by sunlights, containing 800 burners, of No. 3 size. The room is used for public meetings, festivals, concerts, balls, banquets, soirees, bazaars, panoramas, and similar purposes. The committee direct attention to the position of the grand organ at the north end of the hall, and to the form and area of the orchestra, which, upon special occasions, is often occupied by a large body of singers and instrumentalists. This circumstance may suggest the desirability of a slight increase in the quantity of light in the neighbourhood of the orchestra. For the present, the space underneath the gallery will not require to be lighted. Incandescent lamps must be used for the lighting of the Victoria Hall. It is suggested that 500 20 candle-power lamps should be employed for this purpose. The lamps may be distributed in such a manner as may be considered most conducive to the brilliant illumination of the hall, and as will best harmonise with its architectural proportions and ornamentation. If it should be proposed to suspend chandeliers or coronæ from the roof of the hall, sufficient and convenient means of doing so is afforded by the character of the double roof. The present sunlights are fitted with raising and lowering gear. The corporation are in possession of several of the large chandeliers recently hung in the Victoria Hall, the brilliant lustres belonging to which, it has been suggested, might be utilised in connection with the proposed lighting. One of these chandeliers has been fixed in the Town Hall, and may be seen on application to Mr. Linsley, the superintendent. It may be mentioned that the receptacles in the arches, near the roof, at each side of the hall, to which the main pipes of the ten chandeliers were lately affixed, are still available for use.

2. THE VESTIBULE, TOWN HALL.—One arc lamp of 1,000 estimated candle-power to be suspended from the dome in the vestibule, and proper raising and lowering year provided.

THE MUNICIPAL BUILDINGS.

3. THE VESTIBULE.—One arc lamp of 1,000 estimated candle-power to be suspended from the roof, and to be provided with proper raising and lowering gear.

4. THE GENERAL PAY OFFICE.—PLAN NO. 1.—This office will be used for the purpose of receiving rates and rents. The plan indicates the intended position of the pay counter and of the seven desks for the clerks. Plan No. 2 gives the section. Suitable raising and lowering gear to be provided. Four arc lamps of 1,000 estimated candle-power to be emyloyed in the lighting of this and the adjoining office.

5. THE GAS AND WATER OFFICE.—PLAN 3.—The clerks engaged in the work of the gas and water departments will be located at the five desks in this room, and it is suggested that two of the four arc lamps before referred to will be amply sufficient to light the room. Suitable raising and lowering gear to be provided. Plan No. 3 gives the section.

6. THE GENERAL READING ROOM.—PLAN NO. 4.—This plan shows the general arrangement of the tables and stands in the general reading room. The parts marked "A" indicate the intended positions of the newspaper stands, and the parts marked "B" indicate the positions of the reading tables. This department must be lighted with incandescent lamps, of which fifty-one may be employed, arranged in such manner as may be considered most likely to produce a successful result. The three red circles on the plan indicate the positions which may be found most convenient for pendants to each of which six lamps may be attached. The remainder of the lamps (three-three) may be distributed in groups of three each by pendants in the positions indicated by the cross in red on the plan.

7. THE LENDING LIBRARY.—PLAN NO. 5.—The public will resort to this portion of the free public library for the purpose of borrowing and returning books. The plan shows the intended position of counters, bookcases, indicators, and recesses. The "indicators" are frames 4ft. high, standing upon the counters, in the positions marked upon the plan, and show, by a small numbered tablet, whether a book is "in" or "out." One of these "indicators" may be seen at the Free Public Library, in Infirmary-street, Leeds. Incandescent lamps must be used for the lighting of this department. The places marked "Xa" on the plan show the suggested position of pendants in groups of two lamps each. It will be seen, on reference to the plan, that the areas of the spaces so marked are only small. The total number of lamps suggested to be employed in the lighting of this room will be seventy.

8. THE REFERENCE LIBRARY, LOWER LEVEL.—PLAN NO. 6.—This

Digitized by Google

plan shows the intended arrangement of the counters, book-cases, tables and recesses in the reference department of the library. The parts marked "a" are tables or counters, to be used for purposes of reference to books, and the parts marked "b" are writing tables. Incandescent lamps must be used for the lighting of this department. The places marked "Xc" show the suggested position of pendant lights, also in groups of two. The total number of lamps proposed to be used in this room will be sixty.

9. The Reference Library, Upper Level.—Plan No. 7.—This plan shows the proposed arrangement of bookcases, writing tables, and recesses. Incandescent lamps must be used for the lighting of this department. The places marked "b" indicate the positions of the writing tables, and the places marked "Xc" indicate the suggested position of pendant lights, also in groups of two each. The red circles on the plan mark the suggested position of clusters of twenty lamps each, *i.e.*, forty in all. Round the space marked "open well," short standards, with two lamps each, sixteen altogether, should be placed, to light the sloping stands which it is intended to place there. The total number of incandescent lamps to be used in this room will be eighty. Plans 8 and 9 show a section through the library division of the building, and illustrate the area to be lighted in the general reading room, the lending library, the reference library, and the upper reference library.

Outside Lighting.—Four arc lamps to be placed outside and in front of the Town Hall. The present standards may be utilised.

In Calverley Street.—One arc lamp to be placed at the Calverley-street entrance to the Town Hall between the two existing gas standards, which may be utilised for supporting the framework of the lamp.

Engines.—The committee propose, at their own expense, to provide suitable engines and boilers necessary for driving the dynamo-machines to be used in connection with any of the tenders they may accept. Each tender must, therefore, contain an estimate of the horse-power required, also a statement of any special matters relating to plant, &c., other than which must also state the means to be adopted to reduce or extinguish any one or more of the lights in any part or section of the system.

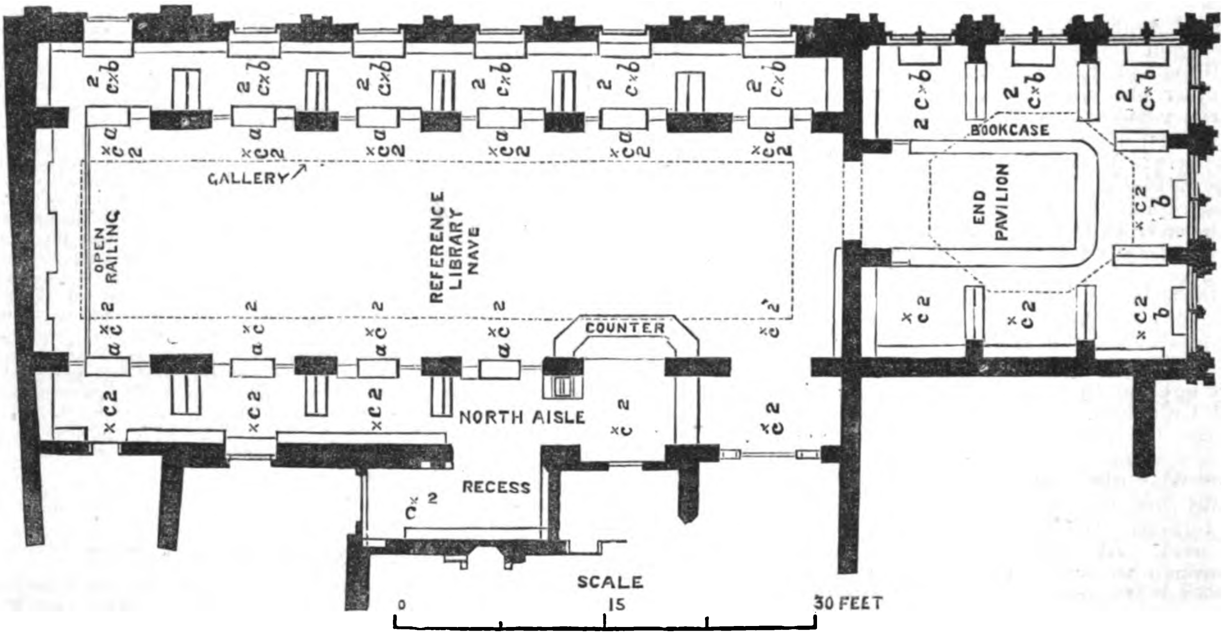
Fire Risks.—The tenders must state what means it is proposed to adopt to obviate the risk of fire from overheating, also if it is intended to carry out the requirements of the insurance companies, as contained in the recommendation of the council of the Society of Telegraph Engineers and Electricians, dated June 21st, 1882, in connection with such risks.

Fittings.—A short description of the fittings to be used must accompany each tender, and if it is proprosed to use shades with any of the incandescent lamps, it would be desirable to forward a sample shade with the tender. All wires must be carried to the various groups of lamps by means of wood mouldings, to harmonise with the walls and mouldings of the ceilings, &c., so as to cover up and preserve the wires.

Incandescent Lamps.—"Swan" or other approved lamps of not less than 20 candle-power must be used. The committee will, however, reserve to themselves the right to accept or require to have employed any other description of incandescent lamp of the same candle-power in connection with the proposed installation.

Arc Lamps.—The tenders must state if the person or company tendering are prepared to use, in the proposed arc lightning, any of the arc lamps now before the public, should the corporation desire, for experimental purposes, to make a selection therefrom. It would be desirable, also, if the tenders contained a list of the arc lamps any of which might be used in the proposed lighting, together with any suggestions as to their special suitability for either interior or exterior illumination.

Work and Labour.—The committee will open such parts of the public highways as may be necessary for receiving the receptacles for the conductors, and after the same have been laid therein will fill up and make good the trench. The committee will not, however, accept any responsibility in connection with the laying of the receptacles or cables, but the same and the necessary joint boxes shall be laid by and at the expense of the con-



Plan No. 6, showing the Library, &c., in the Leeds Municipal Buildings, to be lighted by Electricity.

the engines and boilers which the contractor would prefer should be provided by the corporation in connection with this branch of the tender. The contractor must provide and maintain all necessary belting and counter-shafting. Any person or company submitting a tender, who may themselves prefer to provide the whole of the plant and machinery necessary for the complete installation (including engine and boilers), may propose to do so, but are requested to include such items in a supplemental tender showing the additional estimated cost of providing such engines and boilers, &c.

The Power and Dynamo-Station.—The committee propose, at their own cost, to provide, within a distance of 400 yards from, but as near as possible to the Town Hall, a suitable building or place for the engines, boilers, and dynamo-machines, and will, in case the committee should provide the engines and boilers, make all necessary foundations for, and properly fix the boilers and engines ready for starting, after which the power will be delivered to the control, care, and maintenance of the contractors. At the end of the term, or on other sooner determination of the contract, the contractor shall re-deliver the engines and boilers to the corporation in good order and condition, reasonable wear and tear only excepted. The committee will, at their own cost, find and provide the gas, coal, and water, for the agreed term, and will also pay all rates and taxes on the station. The contractor must provide the necessary oil, waste, and petty stores.

Dynamo-Machines.—The tenders must provide for the employment of the Crompton-Bürgin dynamo-machines, for both the arc and incandescent lamp lighting.

Conductors and Leading Wires.—Perfect insulation must be adopted, and each tender must state the character and quality of the conductors and of the leading and connecting wires to be used.

Regulating Apparatus and other Fittings.—A list of the regulating apparatus and other electrical fittings must accompany each tender, tractor. The corporation will at their own cost supply a sufficient quantity of 3-in. iron pipes for containing cables. The contractor shall find and provide (with the exception herein otherwise proposed) all necessary plant and machinery for providing a complete system of electric lighting in the rooms and at the places named, and the whole of the work is to be finished in a workmanlike manner to the satisfaction of the electric lighting committee of the corporation.

The Working of the Plant.—The contractor will be required to place in charge of the installation a competent person or persons to work and carry out the lighting, during the continuance of the contract, the wages of such persons to be separately estimated in the tenders, and to be paid by the corporation. A weekly return shall be made to the committee and to the contractors of the full and complete details of the cost and working of the installation during the preceding week. The committee will reserve to themselves the right to suspend any workman employed by the contractor in or about the installation in the event of such workman not discharging his duties to the satisfaction of the committee, or who may conduct himself improperly, and to require the contractor to immediately replace the workman so suspended by another workman to be approved by the committee.

SUMMARY OF LAMPS.

3 Vestibule, Municipal Building	1
4 General Pay Office	2
5 Clerk's Office	2
In front of Town Hall	4
In Calverley-street	1
Total	11

MAINTAINENCE AND CONTINUATION OF CONTRACT.—The tenders may be for a period of one or two years, and must be in the following alternative form :—1. The total amount for carrying out the whole of the electric lighting mentioned in these particulars, and for maintaining the same in an efficient manner for a period of twelve months from the completion of the installation, the whole of the plant and machinery supplied by the contractor to be removed by the contractor at the end of that term. 2. The additional amount at which the corporation may purchase, at the end of the first year, the whole of the plant and machinery so supplied by the contractor. 3. The total amount for carrying out the same work for a period of two years, the same plant and machinery to be removed by the contractor at the end of the term. 4. The additional amount at which the corporation may purchase, at the end of the second year, the whole of the plant and machinery so supplied by the contractor.

TENDERS.—The Electric Lighting Committee or the corporation do not bind themselves to accept the lowest or any of the tenders. The company or person whose tender may be accepted will be required to enter into a contract, to be prepared by the solicitor to the corporation, to complete the whole of the before-mentioned work within two months from the date of the acceptance of the tender by the committee, such contract to contain such clauses and conditions as may be necessary for carrying the same into effect, and particularly a clause empowering the corporation to determine the contract in the event of the contractor having failed, for a period of one month after the completion of the installation, to have efficiently carried out the terms of the contract during such month; and also a condition for the payment by the contractor to the corporation of a sum of £10 for each and every day during which default is made in completing the installation after the above-named two months.

The Victoria Hall and the vestibule may be inspected on application to the superintendent, and the interior of the new municipal buildings, may be seen on application to the clerk of the works. Sealed tenders and specifications, addressed to the Chairman of the Electric Lighting Committee, Town Hall, Leeds, and marked "Tender for Electric Lighting," to be delivered at the office of the Town Clerk, Town Hall, Leeds, not later than 5 p.m. on Thursday, the 21st June next.

By order of the Electric Lighting Committee,

GEORGE W. MORRISON, Town Clerk.

Town Hall, Leeds, 21st May, 1883.

THE WEST INDIA AND PANAMA TELEGRAPH COMPANY (LIMITED).

The twelfth ordinary general meeting of this Company was held on Wednesday, at the Cannon-street Hotel, Mr. C. W. Earle in the chair.

Mr. R. T. BROWN (the secretary) read the notice convening the meeting, and the report of the directors was taken as read.

The CHAIRMAN said : As far as the accounts go there is very little for me to remark upon them. They are very much the same as they usually are. I shall be very glad to answer any question that anybody may like to put upon them when I conclude. The only feature about them is one that is never absent from our report, which is the lamentable deficiency of revenue. To think that with 4,000 miles of cable, working twenty-one stations in the tropics, we should only be able in the course of the half year to carry traffic for which we receive about £25,000 is something quite unparalleled in the history of telegraph enterprise. It is not to be wondered at when I tell you that at some of those stations we have only three people who use the telegraph, and yet there is a proportionate mileage of cable, there are the ships and other expenses maintained for the benefit of those gentlemen who occasionally use our telegraph. It is therefore not to be wondered at that the revenue is a very poor one. But the question will then arise, How is it that so much capital is invested in such an unprofitable field as this? Well, I think, gentlemen, the answer to that is contained in a document which I hold in my hands. I do not go with those who always criticise the estimate made in a prospectus; they are generally put forth by people in sanguine moments and in hopes that what they state will be fulfilled, but when it comes with a certain amount of responsible authority, as this prospectus certainly did, it has a different complexion to my mind altogether. Now, I will just read to you what is stated in the original prospectus of this Company: "Sir Charles Bright, who has recently returned from the West Indies, has made a report upon the probable revenue to be derived from the Company's lines. This report, prepared from estimates based upon official returns, and the actual results of the existing Cuba line—earning after eighteen months working at the rate of £60,000 a year—fixes the probable receipts from messages on the Company's lines at £156,000 a year, and the working expenses at £20,000 a year." Well, this £156,000 was estimated as our traffic from fewer stations than we serve at present, because other stations were added almost immediately after the formation of the Company, at the earnest desire of other colonies that were not included in the enterprise. But then who were the gentlemen that endorsed this? Well, in looking at the names of the directors I find they are persons of the very highest standing in the West Indian trade and West Indian connections. I think that out of the whole number there are four gentlemen who are intimately connected with the West Indian business. Well, therefore, I think, to a great extent, the West Indies are responsible for the mistake, and it is nothing more than a mistake. Those gentlemen, no doubt, were actuated by the best intentions; they were men of the highest integrity, and believed what they stated, and endorsed this thinking they would have a revenue something like what they put forward. Well, it has turned out a most lamentable disappointment. No doubt the colonies are very much indebted to them for having obtained the capital; they afforded to them very great facilities, they have enabled them to economise for administrative purposes, and the telegraph has been of very great value to the home Government, besides being of very great value to the colonial Governments, and to every merchant carrying on business in those colonies. Well, seeing the manner in which this Company was raised, and the unfortunate result and disappointment as to traffic, I think, as our report says, that there is a certain amount of moral claim on the West Indies for the reconsideration of this contract—the most onerous contract ever entered into by any telegraph company—and for that purpose we have from time to time opened negotiations with them. We have sent out three missions to the West Indies, and I am sorry to say the result has led to very little improvement in our position. It would be a very difficult thing, as you may well suppose, to negotiate with a dozen separate Governments, and when you have brought them most into a favourable view you are thrown over by a final negotiation by one Government which is recalcitrant and obstinate on the subject. The mission sent out with Mr. Grosvenor was followed by a telegraph conference. We hoped that this conference would have looked into the question and seen if there was anything for this Company to live upon, and if there were any means by which the position of the Company could be improved to make it more effectual, and its cables made to carry on the business more to their satisfaction than they did. Well, the conference met, and did not inquire into the position of the Company in the least, but propounded a scheme for laying a cable direct to Bermuda and Nova Scotia. That scheme was submitted to the home Government, and after some delay, owing to reference to the Treasury and Postmaster-General, a report, a very exhaustive report, was issued by the Post Office engineer to the Postal Department upon the West Indian question altogether. It is a very exhaustive report, but there are one or two passages which I should like, with your permission, to read. In the Postmaster-General's letter he says, "Undoubtedly the Company have had great difficulties to contend with, but Mr. Fawcett believes that the present Board are striving to put their property on a sound basis, and notwithstanding the opinion expressed by the conference that the Company have failed to meet the requirements of the West Indian Colonies, he fears that there would be just cause for complaint against Her Majesty's Government if it were now to subsidise a rival company [they asked for subsidies, and intended to subsidise a rival company] especially as such a company would in all probability require not much less support in the shape of subsidies than the present Company lay claim to, and he directs me to observe that he thinks any company would have reasonable ground for objecting to supply the bulletin of news which the Company are called upon to furnish free of charge. No such information is supplied gratis by the other cable companies; it is given in the interests of a class, and the Company must in consequence lose a number of messages that merchants themselves would otherwise have to send." Again he says, "In conclusion, Mr. Fawcett would draw the special attention of the Lords Commissioners of Her Majesty's Treasury to the opinion of the engineer-in-chief to this department that any cables laid under the auspices of a new company would practically not be safer than those of the existing company, and would urge the greatest caution before any support is given to a scheme involving so much risk. It will be seen that in some parts the depth of the sea is enormous, and that the recovery of a cable, if interrupted at such a depth, is problematical; and he would point to the fact that as large a sum as £90,000 has been spent by one of the existing Atlantic cable companies in effecting the repair of a cable lying in a less depth of water." Then I will read to you—it will not take long—the concluding paragraph of the engineer-in-chief. It is a longish report that he gives upon the whole question, but the concluding paragraph seems to me to be important to us, it is all important, but that is particularly important: "Nor is it apparent to me that new cables laid under the auspices of a new company would in practice be any safer than those of the existing West India and Panama Company. They will be liable to the same dangers, resting on the same bottom, be subject to the same difficulties, or impossibilities of recovery, and generally be in no better position, excepting, perhaps, that the new undertakers may be supposed to be pecuniarily stronger, and therefore better able to cope with the difficulties of the position. When the West India and Panama cables were laid there was a want of care displayed by the speculators, the best positions for cables were not sought for, and it is only fair to add that in many cases no sufficient soundings existed for their guidance. Many of the errors then committed have since been rectified, but the Company has grown poorer and poorer, and want of means has prohibited renewal when necessary, or the laying of new cables when evidently desirable. I cannot but think, therefore, that in some fashion or other an improvement of existing means ought to be possible in preference to incurring a great and uncertain outlay for the purpose of partly doing that which, in theory at least, is now done much more fully, exposing the colonies to a total loss of communication to certain quarters, giving them no greater certainty than at present of the maintenance of their communication with Great Britain, and benefiting them only by a probably lower tariff, and the possibility that, for some time at least, the new concern will be financially stronger than the present one. Possibly, also, it is fair to say that the new cable might be expected to be of higher quality than the old, seeing the circumstances under which the latter was made, as well as laid; but what the islands have suffered from has been entire interruption, not from loss of insulation or imperfection of working." Well, gentlemen, those papers, and a great deal else which I could not take up your time in reading now, I felt were very satisfactory to us, because they really do state, in as fair a way as you can expect from official papers of that sort, what we have suffered from, and how little hope there was of the West Indies or anybody else to take our place. However, we felt that it was fair to us, and to the colonies, and to every one concerned, that we should lay before the Secretary of State for the Colonies our views as to what could be done if we have sufficient support. The interruption to our cables is an annoyance, no doubt, to the colonists, and naturally so. Every cable is liable to be interrupted, and ours particularly so; the ground is so bad, and we thought if they chose to pay for it we could lay a new line, which would give additional strength to the whole system. We then had an interview with Lord Derby, in which he, in a business

Digitized by Google

like way, discussed the whole thing. I think he saw that we had a great deal to complain of, and that we had been rather unfairly treated all the way through. We all know the difficulties a minister has to get money; he is on delicate ground when he touches the finances of the colonies, he has no power to say you shall provide proper funds, and the exigencies of the Government in England make it a very difficult thing to help us out of the Imperial Exchequer. We all know with regard to the Cape cable it required a Zulu war and certain disasters to urge the Government to come forward and give a subsidy, which induced the subscription for the great work. But I must mention that while all this has been going on these very colonies whose representatives propounded such a magnificent scheme as the Bermuda and Nova Scotia line are in such financial difficulties themselves that commissioners have been sent out to inquire into the position of their finances, and Lord Derby has intimated to us that if we are corresponding with the colonies on the proposals submitted to him he must wait till he sees these commissioners, who returned the other day from their visit to those colonies, where they have been investigating the position of the colonies, which are in a very embarrassed condition. Therefore, there is nothing for it but to leave the matter in that position. I do not know that it is a very hopeful one, but still we have done all we can in the matter. We are entirely at the mercy of the colonies and the Government, who should see that if they do not help us they will have to go without the telegraph. If they do not see it in that light we cannot do anything more. We have petitioned them, and pressed the matter on them, and we must leave it to their judgment and decision, and sense of honesty I may say, as to whether they will support us or not. The appropriation of the balance is one that I daresay will cause some inquiry in your minds. The putting of an unusually large sum to reserve has, I believe, in the minds of some shareholders excited some question and anxiety, but the fact is that we must be the judges of the position as regards the prospects of the future. We have no right to divide what is really not earned, and seeing the very small amount of our reserve and this year we get a sum as a windfall out of the hire of our ship—we thought it was our duty to put such a sum as we have put, £15,000, to reserve fund. It is our first duty to maintain the system, whatever happens, and hard though it is - and I feel it very much for you and myself also, for I have a considerable stake in the thing—hard as it is, that we should have to set aside a reserve in order to provide all those gentlemen who are employing your telegraph with security of communication, I do not see myself we can help it at the present juncture. One of our cables has never been in operation since the present Board took office, the Jamaica San-Juan; it was laid at the origin of the Company, and we have never had time to repair that cable, and the condition it is in is very problematical. We have a ship working at it now, but we think, taking all these things into consideration, £15,000 is a wise appropriation at the present moment. On the 30th June, 188?, we placed £10,000 to reserve, and carried forward £5,840, and divided nothing, so that our action in this matter is not so abnormal as it would appear, because, as I said before, a considerable sum of this is a windfall which we cannot expect every day. If any gentleman wishes to ask any questions, I shall be very glad to answer them, and, in the meantime, I will propose that the directors' report and accounts to 31st December, 1882, submitted to this meeting, be, and the same are, hereby received and adopted.

Mr. W. FORD seconded the motion.

Some discussion ensued, and

The CHAIRMAN, in reply to questions, said that the expenditure was kept down to the lowest possible point, but it was absolutely necessary to keep two repairing ships, as one could not keep pace with the repairs, and it was found to be more economical, as the subsidies ceased directly there was an interruption.

The report was then adopted, and the retiring directors and auditors having been re-elected,

A vote of thanks to the chairman and directors terminated the proceedings.

THE CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).

Report to be presented at the second general meeting, to be held at the Cannon-street Hotel, on Thursday, May 31, 1883, at 12 noon. The directors beg to lay before the shareholders a statement of accounts and balance-sheet for the year ending March 31, 1883. The directors do not recommend the payment of any further dividend for the past year, the operations of which have in many respects been very disappointing. The accounts show scarcely any transactions with the United Telephone Company. It is not expedient to detail the causes of difference between the two companies, because, since the expiration of the financial year, a satisfactory arrangement has been come to between the two companies, covering a settlement for the past and future relations. The directors are glad to be able to say that in connection with this settlement the United Telephone Company have relinquished to the Consolidated Telephone Company the benefits of an important agreement which the former company has entered into for supplying telephones to the Post Office. In order to extend the Company's business the directors entered into engagements in relation to telephone concessions in Austria, of which they entertain a high opinion, and some of which are already in active operation. The directors also regard most favourably the interests which the Company has in the River Plate Telephone Company. Probably few telephone companies have a better future before them than the River Plate Company. Embarrassed from want of capital, and with the danger before them of possibly having in consequence to sacrifice valuable interests, the directors had to determine to dispose of some of the unissued shares, and the market value left them no option but to do so at a discount. The financial difficulty is now surmounted; but the directors do not think it desirable to divide at present the money that is to be received from the United Telephone Company. When, as it is shortly proposed to do, the Austrian concessions are placed on a separate footing, a further division of profits will be fairly a matter for consideration. A considerable number of instruments are being sent to Australia, India, Egypt, and other parts of the world, under arrangements with the Oriental Telephone Company. The auditors, Messrs. Deloitte, Dever, and Co., retire in pursuance with the Articles of Association, but are eligible for re-election.

ELECTRIC SUN LAMP AND POWER COMPANY.

The ordinary general meeting of this Company was held at the City Terminus Hotel, Cannon-street, on Wednesday; the Right Hon. Lord BRABOURNE in the chair.

Mr. J. REEVE (the secretary) having read the notice convening the meeting, the report was taken as read.

The CHAIRMAN expressed regret that the meeting had been fixed for what had transpired to be the Derby Day, a circumstance of which the directors were ignorant at the time of fixing the meeting owing to their want of racing knowledge. The shareholders would hardly need an apology from him on the part of the Board for having called them together at such an early period. As the statutory meeting of the Company was held at the end of October last, the directors were under no obligation to call the shareholders together until the end of the present year; but they thought it was very desirable, under existing circumstances, that they should meet at this particular time, so that the shareholders might be informed as fully as possible of the position of the Company. After referring to his absence, owing to ill-health, both at the time of allotment of the shares and from the statutory meeting, and observing that the allotment was only proceeded with when the conditions previously decided upon by the Board had been fulfilled, he stated that they had not at the date of the allotment, nor had they at the present moment, any doubt whatever of the ultimate and entire success of the Company. At the statutory meeting Sir James Carmichael (the deputy-chairman) clearly laid before them the position of the Company. Before he (Lord Brabourne) allowed his name to be connected with this enterprise he made every possible inquiry, and satisfied himself, as far as any man not possessed of special knowledge of electricity could satisfy himself, that the Sun lamp was likely to be a great success—an opinion which was not only his but that of others who had seen the manner in which the vaults beneath the Exchange were lighted last year; and that was also the deliberate opinion of men who had made electricity their study and its development their profession. He felt bound to add that up to that moment they had had no reason to recede from that opinion. It might be asked, why, if their lamp was so good, had it not been more fully exhibited, as other electric lamps had been? The answer to that question was, that in pursuance of the policy which the directors had decided upon, they felt that such a good lamp would push its own way, slowly, perhaps, but surely, without wasting money in unremunerative lighting or sensational exhibitions. Considering that electricity was, in a manner, in its infancy, it had also been their endeavour to make the lamp as perfect as possible, and to adopt such improvements as they had suggested from the first, and which had now been carried out by the inventor, rather than to hurry it prematurely before the public. Their object had been to lay the foundation of future success on such a firm basis that when the fabric had once been erected there should be no chance of its overthrow. They had not, however, been idle, but they had pushed the enterprise legitimately and judiciously forward in every way. They had done this both in London and in the country, where they had been quietly laying the foundation of an extended connection, and in the hope that when success began to develop itself, as they believed it would, the progress of that success would be large and rapid. He then referred to the appointment of a managing director, whose business it was to inspect closely the details as to the machinery, as to the manufacture of the lamps, and the installations in the actual every day working of the Company. They had been exceptionally fortunate in securing for this office Mr. Bartley, who had most assiduously attended to the daily business connected with the manufacture of their lamp and its introduction into the world, and he felt it would be better to leave to him any explanation as to the details which the shareholders might require. The Board had endeavoured to work for the interests of the shareholders both in London and in the country. The principle upon which they had worked in the country had not yet been fully tested, for a sufficient time had not yet been given for its development; but they had the greatest confidence that in a short time they would be able to show the results of the country installations in such a manner as to fully justify the policy of the Board in that direction. The total expenses of the country installations had, however, been under £800, a considerable proportion of which still belonged to the Company in the shape of plant. With regard to the London work, he did not wish to conceal from them for a moment that it was in London that the question of their success would be tested and decided. With this prospect in view they had secured eligible premises in Riding House-street, where he believed the exhibition of electric lighting by their lamps on the previous evening gave entire satisfaction. They had, moreover, obtained the approval and support of two vestries in their application to the Board of Trade for licenses, and if those licenses were granted on the terms which they hoped they would be, he did not think there could be any doubt as to the success of the Company. Upon that their success very much hinged. The directors were as anxious as any of the shareholders for a dividend; but, at the same time, the dividend must be earned before it could be satisfactorily declared. It was to be remembered that when money was subscribed for the construction of a railway, until the line was completed, the rails laid, the sanction of the Government inspectors obtained, the line opened, and the traffic operations in full swing, they could not pretend to hope for a dividend; and similar remarks applied to an undertaking such as that in which this Company was interested. There must be a great deal of expenditure not immediately remunerative—he said "not immediately remunerative," because all expenditure judiciously directed became in the end remunerative if the Company was a success. If he were right in his premises he thought the shareholders of this Company might take a great deal of comfort to themselves by remembering the difficulties which were met with by those interested in gas on its introduction, and then thinking of the handsome dividends which were now being paid by the gas companies. If scientific men were right in prophesying for electricity the success which they had predicted for it, he did not see why in a few years time they should not be able to forget their present unremunerative expenditure in the dividends they would then be receiving. At the same time they must not shut their eyes to the difficulties before them, and must recollect that a dividend could not be expected before a sufficient time had elapsed for the development of their enterprise. It was not to be forgotten that since this Company was founded the Electric Lighting Bill had been passed, and that this had placed certain restrictions on them. He did not think they need apprehend that anything in the rules and regulations of the Board of

Digitized by Google

Trade would be unfair or unjust; but until they knew positively what those rules and regulations were, and knew upon what terms they would obtain the licenses for which they had applied, it was impossible to speak with such confidence of their future success as he hoped to be able to do when he next addressed them. The two vestries who had supported them were St. James's and Marylebone, and if the licenses applied for were granted on fair terms they would have before them a very large business—as much certainly as they could undertake with their present capital. There might be conditions imposed with regard to the depositing of money, and with regard to other matters, which might oblige them to hasten a call, or even to ask the approval of the shareholders to a further issue of capital. They did not know whether this would be so, but they must not shut their eyes to the possibility of such an event. Their expenditure had up to the present time, he contended, been wise and cautious. They had plenty of business before them only awaiting the licenses from the Board of Trade, and they had a large reserve of capital which would enable them to prosecute the enterprise, and go on, as he hoped, to promote satisfactorily the success of the undertaking. The policy of the directors would be to act with care and caution, but at the same time with courage, not to be afraid of obstacles, and not to be afraid to ask for more capital if they believed it would ultimately be productive of remunerative results, although they might have to wait a little time for them. He believed there were the elements of success in their light, and that in the manner in which they had dealt with it they had placed the shareholders in no difficulties, and with the expenditure of capital he had mentioned they had brought them up to this point—that if the licenses were granted on satisfactory terms—and there was no reason to suppose that the terms would not be satisfactory—they had a business waiting for them which must in a comparatively short time develop into a considerable state of prosperity. He would remind them that if they did not wish to go on with the enterprise they would sacrifice all the money they had expended—a proceeding which, as men of business, he did not believe they would entertain for a moment. In conclusion, the chairman moved the adoption of the report.

Mr. ROBERT MILBURN seconded the motion.

Mr. JONES asked how they were progressing with the preparations for lighting a portion of the South Kensington Museum?

Mr. BARTON suggested that it might be well to defer the consideration of the call until they knew whether the licenses were granted or not.

Mr. GEORGE C. T. BARTLEY (managing director), in reply, said they were going to light some of the picture galleries at the South Kensington Museum with forty lamps. As the shareholders might be aware, part of the museum was being lit by another system of arc lighting—the Brush—but this Company was going to light the Jones Bequest and four or five long galleries with forty lamps. They had been allotted premises and a place for engine power, and they would be paid the same price as was now being paid for gas—from £2,000 to £3,000 a year, the total gas bill for the museum being about £8,000 a year. They calculated that they would be able to carry out this lighting arrangement at a price which would leave them a profit of £100 or £150 a year; but if the thing were a success the museum authorities would be only too glad to let them light up other portions of the building. Indeed, they had already offered to let them do so, and if the station succeeded as well as they believed it would, and they lit up the whole of the museum, the result would be very profitable indeed to them, and the authorities might buy up the whole of the plant. With regard to the central station, that had been a great source of expenditure; but it had been necessary to have such a station to show their *bonâ fides*, and to show that they were not a merely speculative affair. At their station in Riding House-street they had been able to show their light on a sufficient scale to prove to the vestries that they were in earnest, and the vestries of St. James and Marylebone had so cordially supported their application for the licenses that he had no doubt that they would be granted. He had been to the Board of Trade several times, and he had found the authorities there perfectly in earnest, and as he had been able to show the *bonâ fides* of the Company he had no doubt the licenses applied for would be granted on very reasonable and proper terms. With regard to the country installations, the plan adopted had been to charge a small proportion of the cost—about the amount which those applying to them had been spending in gas, and at the end of the term fixed upon they either sold the plant or took it away. At Bradford they had been lighting up a portion of a very large iron works with entire satisfaction, and he believed that before long the whole of those works would be lit by them. This would, he had no doubt, be a very profitable source of income to the Company, as it would make their light known in an important centre. Careful experiments had been necessary to bring the lamp to its present state of perfection, and to enable each lamp to be turned on and off at pleasure. Great difficulty had been experienced in getting the things made which they required, and especially in obtaining dynamos; but they were now ready for their autumn campaign. In the North of Scotland their light had given the greatest satisfaction, and experiments were being made to make use of the water-power in the district. The people there had seen several other lamps; but theirs was the only one they would have at any price.

In reply to questions, Mr. BARTLEY added that the lease of the Riding House-street premises was thirty-five or thirty-six years. If they were to defer making a call until they had the Board of Trade licenses their works would be stopped, and everything would be at a standstill. Unfortunately, the Board of Trade were rather slow in their operations, and the Company were getting everything ready in view of their sanction. So confident was he that they would get the licences that he thought they ought not to wait, and it would be very inconvenient not to make a call, and shut up their place. The principal vestries had this sunlight. He hoped that the picture galleries at South Kensington would be lighted up in about three weeks. They would only have their large lamps there—1,000 to 1,500 candle-power. The museum authorities would regulate where they would put the lamps.

A SHAREHOLDER said that he had been informed by opponents that a greater amount of horse-power was required to work the sun lamp than any other.

Mr. BARTLEY stated that the Company's engineers, Messrs. Sabine, had gone into the matter very carefully. For his own part he must acknowledge that he was not sufficiently technical to be able to tell them exactly the horse-power that they proposed. As soon as their works were going in Riding House-street they were carefully to test this matter. Till that was done he would rather not commit himself, and it was a matter which could only be verified by a long series of experiments carried on in a scientific way. The station would be available for lighting private houses. The area they proposed lighting was a little over half a mile—from the Langham Hotel to Beak-street, and then across, not quite, to Wardour-street. The lighting at South Kensington was specially for the museum. They could introduce any ordinary incandescent lamp to work in conjunction with their own lamp on the same circuit. The only provincial installation which had run out had been at Wolverhampton, and that had not been as successful as they could wish. The fact was that the people there were very anxious to have the light all in a moment, and the Company were perhaps a little unwise in letting them have it before they were quite ready. The dynamo was not quite in order, and the lamp was not of the best type. Something had broken down, which was not a very satisfactory feature. That was the only place, however, where they had any difficulty. They had no doubt that at Bradford they would have a great success, as well as at Glasgow and other places. The experiment at Wolverhampton was tried for three or four months, but the firm which tried it had changed their business, and removed to another town, some 50 or 60 miles off, where they were not going to manufacture. The Company had enough capital to take the two districts they proposed lighting, but they could not further extend their system without an increase of capital. They had plenty of evidence that private people in their district would take the light if they could get it as they could get gas, and that was the object of the Company having the central station.

The CHAIRMAN, in further reply, stated that if they increased their capital it would be in consequence of the success of their working with their present capital, which would, therefore, be satisfactory. He thought that Mr. Bartley had fully shown the wisdom of not deferring the call. They had produced the results which he had intimated by means of half of their present subscribed capital, and he thought they could stand comparison with any other company which had come before the public in a similar manner. At the end of seven years the local authorities had the power to acquire their plant, paying them compensation which they must hope would be commensurate with the success achieved by the Company. The vendors had received all that they did receive in cash. There was a balance of £19,950 to be paid over in shares or in cash, and if not paid in cash by 31st December, they could compel the vendors to receive shares. The vendors had, however, shown such liberality towards them that they apprehended no difficulty with them.

On the motion of Mr. JONES a vote of thanks was passed to the chairman and the directors.

The CHAIRMAN briefly replied, and pointed out that the directors were as much interested as the general body of the shareholders in the success of the Company.

The proceedings then terminated.

THE MAXIM-WESTON ELECTRIC COMPANY (LIMITED)

The adjourned meeting of this Company was held on the 18th inst., at the Cannon-street Hotel, Admiral Sir E. A. Inglefield in the chair, for the purpose of receiving the resignation of the directors, and also confirming certain resolutions increasing the capital of the Company.

The SECRETARY (Mr. T. R. Comyn) having read the notice convening the meeting,

Mr. G. MANDER ALLENDER said that before commencing proceedings he wished to ask one or two questions. A circular had been issued to the shareholders from the office of the Company, Cannon-street, signed by Mr. Hugh Watt; that circular contained some positive assertions with regard to figures, and he wished to ask if it was an official circular.

The CHAIRMAN: No, it is not.

Mr. ALLENDER: Being dated from the office I thought it was.

The CHAIRMAN: I may say the Board of Directors as a body knew nothing of the circular. It was not sent to them. I only saw it accidentally by its being sent to me by a shareholder. The Board know nothing of it officially.

Mr. ALLENDER asked the chairman if he endorsed the figures given by Mr. Watt?

The CHAIRMAN: Most certainly not. If I could I should have been very faulty in not bringing the figures forward at the last meeting and saying we were making a profit at the rate of £10,000 a year.

Mr. ALLENDER would like to say, as a member of the late committee, he did not believe in the figures, and could not endorse them, and he challenged Mr. Watt to prove their correctness before a committee of shareholders of this Company. If Mr. Watt were right, then he was wrong, and he would ask Mr. Watt's pardon. If Mr. Watt were wrong it would be for those gentlemen who had supported him to ask themselves whether their proxies had not been obtained by unfair means.

Mr. WATT said that it was incorrect to suppose that he had obtained proxies on the circular he had issued. On the first occasion he held proxies for 30,000 shares. They were not used on that occasion. He held proxies now for over 50,000 shares, but those proxies were not secured by means of his circular. They were obtained chiefly at his own expense by personal canvass. What he asked the shareholders was, whether they wished to retain him on the Board? If they did not wish him to remain he wanted them to say so, as he had no desire to force his services on the Company. He contended that the figures in his circular were correct, provided all the production were sold, and that the profit would then be £200 a week.

The CHAIRMAN said the manufacture of an article and its sale were two different things. They had 10,000 Maxim lamps in their cellars, and were still making them. When they had a large number of lamps in store they must not reckon the profit on them until they were sold. He would now read a letter which he had received from Mr. De Kabath, a gentleman who represented the American company who sold to this Company the Maxim and Weston patents. The letter was dated the 15th inst., and in the course of it Mr. De Kabath stated:— "Answering your request for me to join the Board of the Maxim-Weston

Electric Company, I will say that I have no objection to join the Board with yourself as chairman, and such other parties as you have named to me already as members of the Board, and I feel certain that we will make as great a success of this business here in England as it is already in the United States, and, to some extent, on the Continent. . . . We have to-day, in New York alone, five central stations for the purpose of supplying light, each station is fitted with engines of 500 horse-power, and ample space to allow for the duplication of the plant. We have also installations in the principal buildings: to mention a few, the 'Equitable,' 'Hoffman House,' and about one hundred others. The company's works at Newark, New Jersey, cover a large area, and about one thousand men are employed: four dynamo machines are turned out daily, which forms a total of 1,200 dynamo machines alone per annum, and they have orders for sixty days ahead. The United States Electric Lighting Company paid to their shareholders last year a dividend of five per cent. on their shares, besides carrying over a large reserve. . . . Its sub-companies, the New York Illuminating Company, the New England Weston Company, the companies in Pittsburgh, Louisville, Chicago, Charlestown, and elsewhere, are doing equally well. Estimating roughly, as the business is steadily increasing all the time, I can say that there are not less than 20,000 Weston arc lights in actual daily operation throughout the United States, and not less than 50,000 Maxim incandescent lamps. I think these figures speak for themselves, and I need not add anything to their significance, but I must remark that the business in store for the United States Company is much larger than anything that could be to-day foretold. Messrs. Weston and Maxim are the ablest electricians living to-day. Mr. Weston is now actively engaged in bringing out a complete system for transmitting power by electricity. The experiments which I have witnessed myself were most conclusive. . . . Being myself the owner of some inventions and the representative in Europe of the Maxim and Weston systems of electric lighting, I must not presume to criticise other systems. . . . I must, however, say that having overcome all the difficulties we had to encounter, both in America and Europe, in my opinion there can be no doubt that these two systems, Maxim and Weston, are to-day the very best, both for incandescent and arc lighting. . . . The renewal of lamps forms an important item in working expenses, and the fact of its long life makes the Maxim lamp the most economical one. We have neither been idle on the Continent. The Compagnie d'Eclairage Electrique have purchased our patents for France. It might interest you to know that the price paid by that company for the French patents was very nearly the same as that paid by the English company for the English patents. The French company is now working two systems, viz.:—The Jablochkoff for arc lights, and the Maxim for incandescents; they own also the Weston system, but could not work it, as the French law makes it obligatory to manufacture the apparatus in France. We have been most successful also in Spain, where there are some 40 or 50 plants of our incandescent lamps in actual operation. In Austria, where this summer a large International Electric Exhibition takes place, we shall be well represented, the United States Electric Lighting Company having already forwarded the necessary machines and apparatus. I might mention also that in Vienna we are the only incandescent light system to be seen, having two plants in successful operation for the last six months. In Italy both our systems are well represented. One of our incandescent installations has been visited by the Royal Family, and the Duke d'Aosta expressed a desire to have our light in his palace. We shall be largely represented at the coronation of the Czar of Russia. We have also a great many plants in operation in Germany, Sweden, Norway, Denmark, Belgium, and Holland. To conclude, I will say that I am not of the opinion held by some gentlemen, that the present difficulty of the Maxim-Weston Company in London is to be solely attributed to bad management. I think that the great difficulty that this Company has had to encounter is insufficient capital. No manufacture can be fairly established without the means of establishing a factory, and it is also most essential to have ample funds for working expenses at the outset. This latter is a very important point with electric companies, as the capital must be laid out in plants, central stations, &c. We have up to the present been endeavouring to accomplish certain things which it was impossible to attain without the means necessary for their accomplishment. Can one imagine a gas company being started in London with a capital of £100,000 or £200,000? The capital of a company must correspond to the business it proposes to carry on. . . . . That electricity can be commercially employed is fully demonstrated by the United States Electric Lighting Company, and I have not the slightest doubt but that it can be similarly used in Great Britain if there are adequate means, and the business be conducted with the same amount of enterprise as it has been in the United States." Continuing, the chairman said that, on receipt of that letter, having obtained Mr. de Kabath's consent to nominate him on the Board, he sent in the paper to do so, as he thought in proper time, but unfortunately the letter which he sent in was, according to the Act of Parliament, a few hours late. He nominated also another gentleman, Mr. Allender, who was on the committee of investigation, and he thought that would be an excellent name to bring before the shareholders for election as a director; but unfortunately the same objection applied in this case also. He had therefore been obliged to seek some other way in which those gentlemen could be elected. They would ask the shareholders to elect certain directors today, and in addition two gentlemen, who, if elected, would be ready to retire afterwards, in order that their places might be filled up by the gentlemen whom he had named. With that he placed his own resignation in the hands of the shareholders.

Mr. INVERARITY said that there was no doubt that this was a crisis in the Company's affairs; but the Company was a good one. Their patents were excellent, and it only required a little more time and money and good management. He entirely endorsed what Mr. de Kabath had said. It was hardly fair to the directors at this early stage to accept their resignation, as it amounted to a vote of want of confidence in them. He proposed that the resignations of Admiral Sir E. A. Inglefield and of Mr. Swaby should not be accepted. They were both hard working men, whom he could recommend as directors, and he suggested that they should elect Mr. de Kabath and Mr. Allender as their colleagues. They should leave those gentlemen to settle any differences with Mr. Watt. He must, however, state that Mr. Watt had been of great service to the Company, and had saved it from many disasters.

Dr. THOMAS seconded the motion.

The CHAIRMAN said he had not the slightest wish to remain a director of this Company. He had worked at it for two years, and brought it to a certain point, and he believed it had nothing but success before it, but when gentlemen like Mr. de Kabath and Mr. Allender begged him to remain he gave way.

The motion not to accept the resignation of Admiral Inglefield was put separately, and carried with one dissentient.

It was also resolved unanimously that the resignations of Sir H. B. Sandford and Mr. L. Swaby should not be accepted. The resignation of Mr. Watt was rejected with a few dissentients.

Messrs. S. Gray and J. Brown were elected directors, on the understanding that they would retire for the appointment of Messrs. de Kabath and Allender.

The following resolutions, passed at the previous meeting, were then confirmed, viz.:—"That the nominal capital of the Company be increased by the addition thereto of 327,500 shares of £1 each beyond the registered capital of £172,500, in 172,500 shares of £1 each, making the total capital £500,000," and "That such 327,500 shares may be allotted at the discretion of the directors, on such terms and at such times as they think fit, and either at a premium or at a discount."

A vote of thanks to the chairman and directors then terminated the proceedings.

NOTES.

South America.—The cable between St. Elena and Payta is interrupted.

Birmingham.—The head telegraph office at Birmingham is to be enlarged.

Electric Light in Quebec.—It is stated that arrangements are being made for lighting the harbour of Quebec by electricity.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended the 25th ult. amounted to £2,919.

The Edison System in Queensland.—The Government printing office at Brisbane, Queensland, has been lighted with Edison's incandescent lamps.

Electric Light in Canada.—News from the Dominion states that the city of Hartford having tried a system of electric lighting on a limited scale, was about to utilise it to the fullest extent.

Business Notice.—Messrs. Walter T. Glover and Co., wire makers, of Manchester, inform us that they have opened offices at 85, Buchanan-street, Glasgow, under the charge of Mr. A. B. Spence.

Trinidad.—Recent news from this island stated that Mr. Gray, agent to the Tropical American Telephonic Company, had been in the colony with the object of establishing a telephonic exchange in the capital.

Telegraph Construction and Maintenance Company. —The Bill by which this company are going to extend their powers, so as to include electric lighting, &c., was read a third time in the House of Commons on Thursday, the 25th of May.

London Platino-Brazilian Telegraph Company.—The revenue of this company for the month of February is estimated at £2,115 (Western Brazilian portion £1,424, land lines £691), as against £2,227 for the corresponding period of 1882.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 25th May, 1883, were £1,931, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Brooklyn Bridge.—This bridge, which unites New York and Brooklyn, has just been opened with great pomp. It is a wonderful piece of engineering enterprise. It is to be lighted by arc lamps, the United States Electric Light Company having obtained a contract for the work.

The Telephone in British Guiana.—The annual subscription to the proposed telephonic exchange in Georgetown has been fixed at 60 dollars, and it is feared that this rate will be held to be prohibitory to many persons who are desirous of becoming subscribers.—*Colonies and India.*

Electric Light on Ships.—The ss. "Adelaide," now finishing at Messrs. D. and W. Henderson and Company's yard, Partick, near Glasgow, is to be lighted throughout with the incandescent system. The work has been entrusted to the Edison Electric Light Company, who, with a single exception, have now in hand all the electric lighting on Clyde shipping.

The Fisheries Exhibition.—The entrance vestibule and the Fine Arts Gallery at this exhibition will be lighted by means of 350 Woodhouse and Rawson incandescent lamps, the necessary current being supplied by an Elphinstone-Vincent dynamo. We shall refer to the lighting of this exhibition at greater length when the arrangements are in a more complete state than they are at present.

Electric Light in California.—It is stated that the California Electric Light Company has made a proposition to replace 1,700 gas lamps of 16 candle-power, maintained at a cost of 77,350dols. per annum, in San Francisco, with 210 electric lamps, aggregating 420,000 candle-power, for the sum of 65,520dols. per annum. These lights are to be set upon 40ft. poles at the crossings of every alternate street.

Electric Light in Chemical Works.—The chemical works of Messrs. Barnes and Co., Hackney Wick, are now lighted by means of a Lumley dynamo and sixty 20 candle-power incandescent lamps, thus enabling work to be carried on day and night without intermission. Where combustible and explosive materials have to be handled, there can be no safer or better light than is afforded by the incandescent system.

Electric Lighting in Theatres.—Part of the Gaiety Theatre, London, is to be lit up with Swan lamps, the current being supplied by the Electric Storage Company's accumulators. The branch wires will be laid in Longden-Welch's patent grooved slate. The contract has been obtained by Mr. H. Bury, of 46, Market-street, Manchester, who, we believe, is also to light up the Princess's Theatre in that town.

Electric Light Towers.—One of the electric light towers, as they are called, which have been erected at Fairfield, Indiana, U.S., came down with a crash on the 9th of last month. The cause of the disaster was a heavy gale of wind. The tower was 175 feet high, and had six Brush lamps on it. In falling the tower carried away a considerable length of the telegraph wires belonging to the Western Union Company.

The Telephone for Collieries.—The Mitchells Main Colliery Co., near Barnsley, have adopted the telephone between their chief offices in Barnsley and the collieries near Wombwell, a distance of five miles. One of the lines is carried into the workings in order that the manager may speak from Barnsley direct into the pit. The Johnson-Bell telephones are used, and have been fixed by Messrs. Tasker, Sons and Co., of Sheffield.

The Telephone in the Provinces.—In our issue of May 5th we mentioned that telephonic communication was about to be established between Carlisle and Silloth, a distance of twenty-three miles, for Messrs. Maxwell and Sons, chemical manufacturers. The communication has since been completed with Johnson-Bell telephones, and the results are stated by the local press to be exceedingly satisfactory, notwithstanding that the wire is erected on the railway amongst the ordinary working wires.

Railway and Electrical Appliances Company.—Vice-Chancellor Bacon has made an order for the appointment of Mr. John Young, public accountant, London, as provisional liquidator of this company, whose works are at Glasgow. The petition for liquidation, which was heard last week, was presented by the Duke of Manchester and others, and it appeared that there were as many as seventy-five actions against the company by shareholders desiring to be relieved of their shares.

Electric Light in Factories.—One of the large spinning and weaving factories of the town of Bolbec (Seine Inferreure) belonging to Messrs. Lemaitre, Lavotte and Co., has been lighted for some months past by means of incan-

Digitized by Google

descent lamps. The installation comprises 350 Swan lamps, fed by two Siemens alternate current machines with their exciters. A third is held in reserve, should one of the other two fail. The managers of the factory are so pleased with the new light that they have just ordered 165 new lamps. When these have been fitted up the whole of the work rooms will be lighted by means of electricity.—*L'Electricité.*

UNITED v. LONG DISTANCE TELEPHONE COMPANY.—On Friday, the 25th May, before Mr. Justice Chitty, the United Telephone Company moved for an interim injunction to restrain the defendants, until the trial of the action, from using, manufacturing, or selling instruments made according to Hopkins's patents, which they claimed to be infringements of the Bell and Edison patents. Mr. Aston, Q.C., and Mr. Moulton were for the plaintiffs; and Mr. Macnaghten, Q.C., and Mr. Davenport for the defendants. It was arranged between the parties that, without prejudice to any question in the action, the defendants should give an undertaking in the terms of the notice of motion, and the plaintiffs should give an undertaking in damages.

GLOBE LIGHTNING.—Dr. Henry Muirhead, of Cambuslang, Scotland, gives the following account of a fire-ball seen by his sister many years ago at the farm of Haggs, Glasford Parish, Lanarkshire, in *Symons' Meteorological Magazine* for May:—"During a fearful thunderstorm the farm hands were eagerly striving to cut and bring in a load of grass, but were obliged to give over in consequence of the lightning playing vividly on the scythes and forks. In the thick of the storm my sister saw a ball of fire, about the size of a boy's head, settle down on the ridge of a thatched outhouse. After remaining a few seconds, it fell gradually to pieces or powder, in a manner like to a shell of quicklime when slaked, the gleaming powder streaming down the thatch amid the pouring rain, but doing the roof no injury. If there was any noise from it, it was unheard."

ELECTRIC LIGHTING FOR MUSEUMS.—In the House of Commons, on Thursday week, Mr. Coope asked Mr. Shaw-Lefevre whether he was aware that the electric light had been used in the South Kensington and Jermyn-street Museums for upwards of two years without any accident occurring; whether he was aware that a code of regulations had been adopted jointly by the electric lighting companies and the fire insurance offices, reducing fire risks to a minimum; and whether he was prepared to take measures whereby the National Gallery and the British Museum might be lighted by electricity? To which Mr. Shaw-Lefevre replied that while admitting all that the hon. member had said to be true, he still remained of opinion that we have not had sufficient experience of the electric light to justify him in advising the trustees to use it in the National Gallery.

ELECTRIC LIGHTING AT BUCKINGHAM PALACE.—On the occasion of the State Ball at Buckingham Palace on Tuesday night, the ball room was most brilliantly lighted by means of 700 Swan incandescent lamps. The work of fitting up the lamps, wires &c., was carried out by the officials of the royal household under the superintendence of Mr. W. H. Massey, a well-known electrical engineer, assisted by Messrs. E. H. Liveing and A. H. Walker. The work was carried out in a very short space of time, and for a week before the night of the ball, those concerned were engaged night and day. The result was a grand success, and we believe that H.R.H. the Prince of Wales was very pleased with the lighting. The incandescent system is to replace gas on all state occasions for the remainder of the season. We shall hope to be able to give our readers some further details of this installation in a future issue.

A NOVEL IDEA.—Bazaar promoters, who are fond of novelty, cannot do better than follow the example which has been set them at St. Peter's Church, De Beauvoir-square, in the north of London. Here we are introduced to a fancy fair, which is being held in the crypt of the church; it was inaugurated on Wednesday, and is to last until Saturday (to-day). The crypt being dark even when the sun is at its full power, it was necessary to find some means of dispelling the darkness. Mr. Wharton, of the firm of Laing, White, and Wharton, of Holborn Viaduct, was called in, and has succeeded in lighting up this weird locality for a fancy fair, with something more than a "dim religious light." He has fitted up between 40 and 50 Swan lamps of 10 candle-power, the current being obtained from 54 cells, supplied by the Duplex Electric Light Company. The total current given is about 60 amperes. The lamps are in use from 3 o'clock until 10:30 or 11 p.m., and burn with great steadiness. The whole of the work has been carried out under the personal superintendence of Mr. Wharton.

ELECTRIC LIGHTING FOR GREENOCK.—At the last meeting of the Greenock Police Commissioners, a special sub-committee of the Law and Finance Committee submitted a report with reference to electric lighting, in which they proposed to make a written and personal representation to the Board of Trade, asking that the water-power of Greenock might be utilised, and that an extended period for experimental purposes should be conceded to the burgh. A report by Mr. S. Stewart. gasworks manager, giving an estimated cost of the proposed experiments within a limited area in the Sixth Ward, was also laid before the meeting. The area, it was stated, was bounded by Prospect Hill, Ann, Roxburgh, and Mount Pleasant-streets. The length of streets in the area was about 3,600 yards, and the power for lighting would b got from the Water Trust Premises at Prospect Hill. Mr. Stewart proposed to put up only eight arc lamps in the meantime, if the arc system were adopted, at a total cost of £1,000. He, however, recommended the incandescent lamp, and 90 to 100 such lamps fitted on the existing gas lamp-posts, together with every accessory, he estimated to cost £1,000.

ELECTRIC LIGHTING IN WESTMINSTER.—At a special meeting of the Westminster District Board of Works, presided over by Mr. Thomas Horn, on Wednesday, the parliamentary committee presented a correspondence with the Board of Trade with regard to the applications for provisional orders from electric lighting companies, and they recommended the Board to continue their opposition to the present introduction of electricity in their district, and to maintain such opposition throughout this session of Parliament. After a long debate it was resolved by a two to one majority, on the motion of Mr. Stewart Helder, seconded by Mr. J. K. Aston, "That the Board of Trade be informed that they (the District Board) did not think that the present requirements of the district justified them in negotiating with the promoters of provisional orders for the supply of electricity; and that they think no orders are necessary at the present time." The parliamentary committee were instructed to oppose the schemes mentioned in Major Marindin's report, and it was further resolved that the opinion of the parishioners should be tested by a public meeting on the subject.

ELECTRIC LIGHTING IN LONDON.—We understand that Major Marindin, the officer appointed by the Board of Trade, has made his report on the inquiry held at the Westminster Sessions House on May 10th, and that, as regards the St. Giles District, a provisional order has been granted to the Pilsen, Joel, and General Electric Light Co. (Limited), by arrangement with the local authorities. The area to be

Digitized by Google

lighted by the Pilsen Joel Company will be the south side of New Oxford-street and High Holborn, from the centre line thereof, extending from Tottenham Court-road to Little Queen-street, and the houses, premises, and buildings abutting thereon, and an area bounded on the north by the centre line of High Holborn, from little Queen-street to the boundary of the parish of St. Giles-in-the-Fields, on the east by the said parish boundary line, and on the south by the houses on the north side of Lincoln's Inn-fields and the houses on the south side of Twyford's-buildings, and on the west by the houses on the west side of Little Queen-street. The Pilsen Joel Company have already established a lighting station in that area, and have been for some time past successfully lighting large business establishments from that station.

THE SHOCK FROM A WESTON MACHINE.—A short time since one of the line-men employed by the Citizens Electric Light Company, of Toledo, Ohio, which is running a central station supplying something over one hundred Weston arc-lights, received a shock from two twenty-light machines coupled together and supplying a forty-light circuit. He was making some change in the adjustment of one of the lamps, and took it out of circuit just before the time for starting up in the evening. Before he placed it in position again the current had been turned on without his knowledge, and he accidentally took hold of both terminals of the circuit and received the current from the two machines. The shock was so severe as to close his hands on the wires, and he fell from the step-ladder on which he was standing, his weight tearing him from the wires. His hands were somewhat burned, but he did not lose an hour's time from his work, and suffered no other injury or inconvenience. This shows the comparatively safe nature of the continuous current, as compared with the intermittent or undulatory current, which is used in some of the systems. A similar accident occurred in Boston a short time since, in which a line-man, under the same circumstances, suffered a shock from five ten-light machines coupled without receiving any injury.—*Electrical World*, New York.

THE CZAR'S CORONATION.—During the festivities that have been taking place at Moscow for the last week or so in honour of the Czar's coronation, that city has been illuminated from the top of her highest church spire to the lowest window ledge. Electric lamps have played a conspicuous part in the illuminations, and unlike the oil or tallow lamps that have also been used, have not been put out by the rain which has fallen at frequent intervals. Amongst the other buildings that were brilliantly lit up was the British Embassy. One hundred and twenty Swan lamps were arranged in decorative devices on the façade of the building, and produced an effect which is spoken of by the correspondents of daily papers as the greatest success of the illumination. The current was supplied from Bürgin machines, driven by a Robey engine, situate about 300 yards from the Embassy. The lamps were fitted on to a special form of holder, designed by Mr. A. P. Lundberg, which has been found to resist the action of the wind better than the original spiral form of spring holder, adopted by the Swan Company. Several trials were made with different coloured globes for the lamps, but, on the whole, Sir Edward Thornton considered that the effect of the white globes was the finest. This installation was carried out by Mr. N. W. Hornstedt, the British Vice-Consul, under the personal supervision of Mr. Norcliff Thompson, the London manager of Messrs. Crompton, Winfield and Co., the manufacturers of the machines.

LEGAL.—THE TELEPHONE SUIT.—The case of the United Telephone Company *v.* the London and Globe Telephone Company, mentioned in our note of last week, came on again before Mr. Justice Pearson on Friday week (25th May), when Mr. Hemming, Q.C., for the defendants, moved to dissolve the *ex parte* injunction granted on Tuesday week, and reported in our note, restraining the defendant company from interfering with the telephone wires, supports, and apparatus of the plaintiff company. The learned counsel stated that in fourteen out of the fifteen cases of interference mentioned to the Court on Tuesday the wires of the two companies had accidentally come into contact, and if the plaintiffs had communicated with the defendants' engineer the matter would have been remedied at once, nothing being needed but to tighten or slacken the wires. The fifteenth case, in which thirty-six wires running over Gresham-buildings had been bound together by a metal band, was entirely different, the defendant company having purchased the absolute right to set up poles and support and maintain wires over Gresham-buildings. The plaintiff company also claimed the right to carry their wires over Gresham-buildings, and disputed the defendant company's exercise of the right which they had purchased where it in any way interfered with them.—Mr. Justice Pearson said that he should direct the engineers of both parties to co-operate for the purpose of freeing the plaintiffs' wires from obstruction in the fourteen instances, and he should continue the injunction as to the fifteenth instance brought forward until Thursday (May 31).

ELECTRIC LIGHTING FOR EDINBURGH.—On Monday last Major Marindin, on behalf of the Board of Trade, opened an inquiry at Edinburgh regarding an application by the Brush Electric Light Company of Scotland for a provisional order to supply electricity for lighting purposes, &c., within a certain area in that city. The representatives of the local gas companies were in attendance, though the Electric Light Company appears to have left their advocate to fight their battle by himself, as he stated in his opening speech that "he had not the benefit of the attendance of any of the responsible members of the company." For the promoters Mr. Paton, station master at the Waverley Station, Edinburgh, gave evidence as to the use of the Brush light there for some time past, and thought that "it would be a misfortune to revert to any other form of artificial light." Mr. J. B. Howard, who has been connected with Edinburgh theatres for some sixteen or seventeen years, stated that he was having a theatre erected in Grindlay-street in which he intended to use the electric light permanently, having apparently been influenced so to do by the example of the Savoy Theatre, London. He was going to use Swan lamps and Higgs dynamos. Several commercial men were then examined, and gave evidence to the effect that they would be glad to have the electric light introduced into their houses, shops, and works. Having brought forward his evidence, Mr. Graham Murray, for the promoters, then formally moved for an adjournment. This, Major Marindin, said was quite out of the question; in fact, the standing order of the House of Lords would prevent any adjournment being granted. It would be of no practical use whatever, but simply a waste of time. Under those circumstances, considering the absence of any information as to the position of this company, their capital, and their means of carrying out this order, it would be quite unnecessary for those who appeared for the objectors to speak. He would report against the preamble of the Bill. The objectors were awarded costs.

ELECTRIC LIGHTING IN JAPAN.—We take the following from the *Japan Gazette* for April 6 :—"The official trial of the electric lights just erected at the Yokosuka naval

REESE LIBRARY OF THE UNIVERSITY CALIFORNIA
Digitized by Google

arsenal was held last night (Thursday, April 5) by the Admiralty authorities. The apparatus consists of the large No. 8 Brush dynamo electric machine, driving forty lights of 2,000 candle-power each, on a circuit of No. 8 copper wire B.W.G., three miles in extent. The electric lamps are erected in the various machine, carpenter, boat and spar shops, in the two docks, and in the shipbuilding yards. The driving power is derived from two engines used also to pump the water out of the docks, the adjustments being economically arranged so that when the dock lights alone are burning a single engine will do the work. All the workshops are illuminated as by a flood of daylight, and the light in the docks is so brilliant and equally distributed that night work can hereafter be carried on with the same facility as day work. The lights in the docks are arranged with counterweights to lower to any depth, thus throwing the mass of illumination under a ship's bilges, on her bottom, or alongside, as may be required. These arrangements will be of great importance to the arsenal, as the docks have heretofore been so overcrowded with work that ships have been obliged to make application to enter long in advance or suffer the inconvenience of prolonged delay. Night work will now be done, and in fact, if there is sufficient work, of which there is little doubt, double gangs of labourers may be employed, and the uses of the dock will be practically doubled. The electric lights in the shipbuilding yards are placed on standards 25 to 30ft. high, and are fitted with adjustable reflectors to throw the light wherever needed. There are five lights in these yards where several large ships are now on stocks. The Japanese authorities were greatly delighted at the completeness and success of the illumination. The Swan incandescent light was exhibited at the trial, the engine house being thus illuminated. These lamps will be ultimately run from the new Brush accumulator. This important work, the first of its kind in Japan, has been carried out under the direction of Mr. J. Potter, of the Brush Electric Company, the details being executed by Mr. C. W. Phipps, the company's electrical engineer. Mr. Potter also introduced the electric light into Shanghai."

A Telephone Suit in Dundee.—The case of Messrs. Stewart, manufacturers, of Dundee, *v* the National Telephone Company, of the same town, has recently been settled, after considerable delay. The plaintiffs' case was that for the payment of £15 per annum to the company they became entitled to the use of three sets of telephone wires and apparatus at or from Kinnaird Works, Dundee, and Reform-street, Dundee, for five years from October, 1882, and that they were also entitled to communicate by means of the defendants' telephonic service to Forfar, Broughty Ferry, and such other neighbouring towns as might be connected with the defendants' telephonic exchange in Dundee. The company's defence was that they had only agreed to give the local connection. When the case was heard in the Dundee Sheriff Court in November, 1882, judgment was given for the defendants, but on appeal to the Court of Session the case was remitted back to the sheriff to, in the words of the Scotch courts, "allow full proof of the pursuers' averments." Accordingly the case was fully gone into in Dundee, and evidence taken in London by commission and forwarded to Dundee. The result of this fresh trial has been that Sheriff Cheyne has found for the plaintiffs. The latter relied for their case upon the wording of the agreement between themselves and the telephone company. According to this document the defendants agreed to give the plaintiffs telephonic communication between their works and office in Dundee, and "all persons, firms, or stations, whether in Dundee or neighbouring towns, that might during the existence of the agreement be connected or in communication with the defendants' telephonic exchange in Dundee." We quote from Sheriff Cheyne's judgment. It appeared in evidence that the trunk wire between the Dundee and Forfar Exchange was held by the defendants on a lease from the Postmaster-General for one year from the 12th September, 1882. That the conditions of this lease were that they should only allow such subscribers to use the trunk wire as had signed a special agreement with the Postmaster-General, and that the number of subscribers who might use it should be limited to eight. It also appeared that at the date of the action this number had not been reached, and that the plaintiffs were quite willing to enter into the special agreement with the Postmaster-General, but that, until after the action had been brought, they were not aware that it was necessary to enter into any such agreement, nor had they been asked to do so.

Death of Mr. W. E. Sawyer.—The death of this well-known electrician is announced as having taken place in New York on the 15th May. Many of our readers are doubtless familiar with his work on "Electric Lighting by Incandescence, and its Application to Interior Illumination," published early in 1881, by Van Nostrand, in New York, and Spon, in London, which we noticed at some length in our issue of June 11, 1881. Mr. Sawyer was a prolific inventor and had taken out patents for incandescent and arc lamps, as well as dynamo machines, and it is said that just before his death he was turning his attention to electric railways, with the object of patenting an improved system of his own. He was an eminently practical inventor. We find him first brought into prominence through the purchase of his inventions by the first electric lighting company started in America, viz., the United States Electric Light Company, who, it is said, gave him 50,000 dollars for them, and appointed him on their staff at a high salary. His connection with this company was, however, of short duration. We next hear of him as engaged in experiments on a system of incandescent lighting in conjunction with Mr. Mann, the result being the formation of the Sawyer-Mann Electric Light Company, to work the system. This company failed, and was followed by others, all formed to work Mr. Sawyer's patents, which suffered the same fate. He appears to have been one of those anomalies often to be met with in this world, viz.: possessed of great talents, but weak character, extremely clever, but unbusinesslike and unstable. Accordingly we find him often in difficulties, the most serious of which was hanging over his head at the time of his death. It appears that in May, 1880, Mr. Sawyer was boarding in the same house with a Dr. Steele, that a quarrel arose between them, which ended by Mr. Sawyer shooting Dr. Steele. This was on the 5th May. Mr. Sawyer was arrested, and when his trial came on, which did not happen until March, 1881, he was convicted and sentenced to four years' imprisonment with hard labour. Against this sentence an appeal was made, and as Mr. Sawyer was in bad health he was permitted to remain at home pending the appeal. The Court of Appeals affirmed the decision of the Court of General Sessions, and he then sought pardon from the governor. As his health was such that his removal was considered dangerous, he was permitted to remain at his house. The District Attorney consented to delay in moving for sentence for one month, which expired on the 16th May, but before the time had expired he received official notice of the death of Mr. Sawyer. Truly, a pitiful ending to a life which promised so much.

JOHN PENDER, Esq., M.P.

The gentleman whose portrait we give in this number has been and is one of the most prominent figures in the history of submarine telegraphy. Indeed, it may safely be said that but for his indomitable perseverance submarine telegraphy would even now be in its embryo stage. It needs something more than the ordinary qualities of a keen man of business to grasp the possibilities of a new scientific application at its very birth. It needs, too, something over and above the ordinary business spirit to risk the embarkation of a considerable capital, to risk the loss of prestige that would necessarily follow if inducements held forth should lead friends also to largely subscribe capital and then the enterprise should fail; but this is a comparatively small part of the risk which Mr. Pender took upon his shoulders in those early historical days of submarine telegraphy. He, in conjunction with friends, not only embarked and influenced capital, but suggested a policy, foresaw the rocks and shoals upon which the enterprise might be foundered, and so shaped his policy as, if not to avoid them altogether, to make them practically harmless. It will be said that no one man could in these degenerate days emulate Achilles. Perhaps not; yet we have giants in finance, and one, not the least important characteristic of such men, is choice of colleagues. Those who know the co-workers with Mr. Pender will know we do not exaggerate when we say that among them are some of the keenest business men—men with broad principles and far-seeing instincts, not second to any in this or any other country. Alexander must have known the merits of his men when he sighed that there were no more worlds to conquer.

JOHN PENDER, Esq., M.P.

We shall very briefly sketch the career of Mr. Pender. He was born in the Vale of Leven, Dumbartonshire, in 1816, and received his earlier education in the parish school, but later on at the high school of Glasgow. At an early age he entered the counting house of a factory in the Vale, and being accurate and quick with figures, doing well and thoroughly whatever he undertook to do, we find him at the age of twenty-one exalted to the position of manager of the factory. The mere management of a factory, however, did not give sufficient scope to the energies of Mr. Pender, and he established himself as a merchant in Glasgow, buying and selling in home and foreign trade the goods of which he had obtained a thorough knowledge in the factory. A few years after the house extended itself to Manchester, and became one of the leading distributors of Scottish and Lancashire looms. The trade was world-wide, and success followed, not only in the shape of increasing business but in the accumulation of a large fortune.

Mr. Pender joined the Board of the British Telegraph Company at its formation, and retained his seat after the amalgamation with the Magnetic Telegraph Company, till the purchase of inland telegraphs in 1870 by the Government. In 1855 he was an ardent and active supporter of Mr. Cyrus W. Field in the advocacy of an Atlantic cable. The shares in this first Atlantic Company each cost £1,000, and Mr. Pender and his personal friends were among the earliest contributors. The failure of the first attempt only served to increase the persistent advocacy of Mr. Pender in the enterprise, and in 1864 he suggested the formation of the Telegraph Construction and Maintenance Company, to amalgamate the works of Messrs. Glass, Elliot, and Co., and the works of the Gutta Percha Company, and became chairman of the company. In 1865 an attempt was again made to lay the cable, and again failed, but failed in such a manner as to make success almost certain. Mr. Pender (as chairman) suggested that each member of his Board should subscribe £10,000 as an evidence of confidence in the ultimate success of the work, and so £100,000 was immediately obtained. Financial arrangements were made for the balance, the 1866 cable was made and successfully laid, and the 1865 cable picked up in 2,000 fathoms, and put into good working order. Here was a grand success, and proved the wisdom of those who had undertaken the financial part of the business as conclusively as it proved the ability of sailors and scientific men to carry out the work. Mr. Pender's work in connection with submarine telegraphy had but commenced. He saw the necessity for greater facilities for communicating with our Indian Empire and our great Eastern colonies, and in 1869 retired from the position of chairman of the Telegraph Construction Company to devote his whole energies to the laying a cable to India. The British Indian Cable Company was formed, Mr. Pender becoming chairman, and guaranteeing himself £50,000, besides influencing friends to subscribe another £50,000. The cable was successfully laid, but Mr. Pender's aim was to complete a system of cables connecting England with her Eastern dependencies, to be under the sole control of England. Gradually connections were made and duplicated, and finally the various companies controlling these cables amalgamated into one company, the "Eastern Telegraph Company." The extension of the cable system from India eastward was carried on originally by three companies, which ultimately amalgamated to form the "Eastern Extension Company," with Mr. Pender as chairman, since which the work has been going on almost without cessation. More recently still the "Cape Cable" was projected and carried out, principally under the auspices of the Eastern Telegraph Company. To sum up these facts briefly, it may be said that Mr. Pender has advocated and carried out a policy which has united the various systems under English control, whilst retaining an international character for submarine telegraphy. The results have been that Great Britain is now connected with all the important islands in the Mediterranean and the Levant, with our North American colonies, with the vast land line system of the United States, with our Indian

Digitized by Google

Empire and its network of telegraphs, with the Straits Settlements, Cochin China, China, Japan, Java, Australia, and New Zealand.

In politics Mr. Pender is a staunch Liberal, though not one who likes hasty or extreme views. He sat in the House of Commons for Totnes in 1865-6, but his connection with that borough was short-lived. In 1868 he contested the county of Linlithgow, against Mr. M'Lagan, who gained and still holds the seat. In 1872, it an interim election on the retirement of Mr. Loch, Q.C., he offered himself as a candidate for the northern (or Wick) burghs, and had to fight two contests before the election was decided in his favour by a large majority, and since this time we believe he has represented that constituency.

SOME ELECTROSTATIC AND MAGNETIC RELATIONS.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 583, VOL. X.)

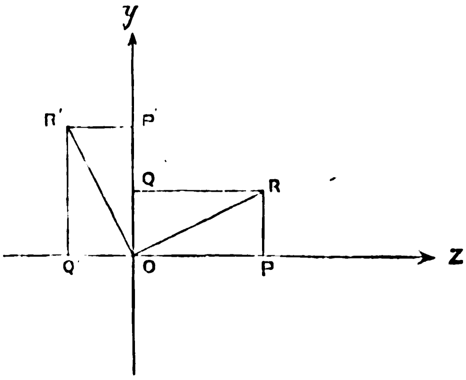
First let X vary in amount only in its own direction, then, in passing from any point through the distance dx parallel to x, X becomes $X + \frac{dX}{dx}dx$, where $\frac{dX}{dx}$ is the rate of increase. Let there be a cubical element of volume $dV = dx\,dy\,dz$, whose edges are parallel to x, y, z, and consider the amount of X entering and leaving the space. Two opposite faces are perpendicular to X, and the four others are parallel thereto. The latter may be disregarded, whilst the amount of X entering one of the first pair is $X\,dy\,dz$, and leaving the other $\left(X + \frac{dX}{dx}dx\right)dy\,dz$, both faces being of area $dy\,dz$. The excess of the latter over the former amount is $\frac{dX}{dx}dV$, that is, $\frac{dX}{dx}$ per unit volume. This is the divergence of the vector in the special case taken, since Y and Z are zero.

Next consider the variation of X perpendicular to x, *i.e.*, in the plane y, z, or parallel thereto. If we start from any point and go in different directions in this plane, X may or may not vary, but if it should do so, there will be in general a certain direction in which it increases fastest, and another direction, crossing the first at right angles, in which there is no variation, just as when one is upon the side of a hill there is a direction of greatest slope at any point, and a level direction perpendicular to the first, disregarding singular points requiring special treatment. $\frac{dX}{dy}$ and $\frac{dX}{dz}$ being the rates of increase of X along y and z, the resultant of vectors of these lengths drawn along y and z is a vector in the direction of most rapid increase of X in the plane y, z, of length equal to the rate of increase. Now, rotate this vector through a right angle in the plane y, z, *i.e.*, about the axis of x, so that in its final position it points along the axis of no variation, it will then represent the curl of X. It will come to the same thing if we rotate the original vectors through a right angle, and compound them afterwards; and by this we see that the components of the curl of X are $+\frac{dX}{dz}$ along y, and $-\frac{dX}{dy}$ along z, when the rotation is left-handed about the axis of x. Let the plane of the paper be the plane of y, z, and the positive direction of the axis of x be downward through the paper at the point O where the variation of X is estimated. Let OP and OQ be of lengths $\frac{dX}{dz}$ and $\frac{dX}{dy}$ respectively. Their resultant is OR, showing the direction and rate of most rapid increase. Rotate the rectangle OPRQO about the axis of x through a right angle into the position OP'R'Q'O, then OR' will represent the curl of X, and OP' and $-$ OQ' its components along y and z.

Now let the vector whose space variation is required be Y everywhere parallel to y, and treat it similarly. We shall find its divergence $= \frac{dY}{dy}$ from the variation in its own direction, and its curl to have components $+\frac{dY}{dx}$ along z and $-\frac{dY}{dz}$ along x, by rotating the resultant space variation in the plane z, x, through a right angle about the axis of y.

And with a vector function Z everywhere parallel to z treated similarly, we shall find its divergence $= \frac{dZ}{dz}$, and the components of its curl to be $+\frac{dZ}{dy}$ along x and $-\frac{dZ}{dx}$ along y.

Finally, if we compound X, Y, and Z, we obtain a vector R, which is arbitrary, and, consequently, may vary both in direction and magnitude from point to point. Its divergence will be the sum of the separate former divergences, or $\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}$, which expresses the whole amount of R leaving the unit volume, reckoned algebraically. And its curl will be represented by the resultant of the three vectors representing the curls of X, Y, and Z (the first being



OR' in the figure, and the second and third two other vectors in planes perpendicular to the plane of the paper and to each other), and its components will be the sum of the former components, and are consequently $\frac{dZ}{dy} - \frac{dY}{dz}$ along x, $\frac{dX}{dz} - \frac{dZ}{dx}$ along y, and $\frac{dY}{dx} - \frac{dX}{dy}$ along z.

17. We thus find the vector curl of R by compounding three vectors which represent respectively the rates of greatest increase in three rectangular planes of the components of R perpendicular to the planes, each of the three vectors being then turned through a right angle in its proper plane. Now this selection and subsequent rotation is effected mechanically when we use the operator ∇ according to quaternion rules. For, if we denote by i, j, k three rectangular vectors of *unit* lengths parallel to x, y, and z, then Xi will denote a vector of length X parallel to x, and similarly for Yj and Zk, consequently we may write $R = Xi + Yj + Zk$ with the convention that the sign of addition signifies compounding as velocities. Now the full expression for ∇ is $i\frac{d}{dx} + j\frac{d}{dy} + k\frac{d}{dz}$, hence

$$\nabla R = \left(i\frac{d}{dx} + j\frac{d}{dy} + k\frac{d}{dz}\right)\left(Xi + Yj + Zk\right).$$

Expand this expression, with the further conventions $i^2 = j^2 = k^2 = -1$, and $ij = k, jk = i, ki = j$, and we obtain,

$$\nabla R = -\left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz}\right) + i\left(\frac{dZ}{dy} - \frac{dY}{dz}\right) + j\left(\frac{dX}{dz} - \frac{dZ}{dx}\right) + k\left(\frac{dY}{dx} - \frac{dX}{dy}\right),$$

i.e., ∇R = convergence R + curl R.

The meaning of the rules $ij = k$, &c., may be interpreted

Digitized by Google

thus: j signifying a unit vector parallel to y, and k another parallel to z, let i be taken to mean, not a unit vector parallel to x, but a rotation through an angle of 90° about x as an axis. Then since j rotated 90° about the x-axis is turned into coincidence with k, we have $ij = k$. Similarly for the other products. As for the squares, we may verify $i^2 = -1$ thus:—Rotate j a second time through 90° about the axis of x. The first rotation brought j into coincidence with k, the second brings it into the same line as at first, but pointing the other way. Thus $i^2j = -j$, or $i^2 = -1$. This use of vectors to denote either lines drawn in definite directions, or else rotations about such lines, is the foundation of the great simplicity and conciseness of quaternion operations and expressions; it is justified by the already mentioned identity of the rules for compounding velocities and rotations, and by its always leading to results which are found to be correct when expanded; but it must be confessed that this double use of the same symbols makes it difficult to establish the elementary parts of quarternions in an intelligible manner. However, this is merely parenthetical, and we shall have no more concern with quaternion expressions beyond noticing that the properties of the quantities defined in section 8 (p. 559 ante), relating to an arbitrary system of magnetic force B, divided into two systems B_1 due to current C_1, and B_2 due to magnetism C_2, may be thus formally expressed. Since ∇ operating on a scalar function gives the vector rate of greatest increase, and on a vector gives its convergence and its curl, or its curl only if it has no convergence, and conversely, we have simply

$$\nabla Z_1 = A_1, \quad \nabla A_1 = B_1, \quad \nabla B_1 = C_1, \quad \nabla C_1 = D_1;$$
$$-\nabla Z_2 = A_2, -\nabla A_2 = B_2, -\nabla B_2 = C_2, -\nabla C_2 = D_2.$$

In the first line, the ∇ signifies "curl" only, because the quantities are vectors of no divergence. In the second line (relating to the magnetism) it is convergence when operating on a vector, and the vector rate of increase when operating on a scalar. The presence of the $-$ sign all along the second line makes it awkward to combine the quantities consistently as they stand. But by simply changing the sign of C_2 and A_2, so that C_2 when positive represents S. magnetism instead of N. we get things straight. Z_2, B_2, and D_2 are unchanged, and denoting $-C_2$ by C'_2 and $-A_2$ by A'_2 we have

$$\nabla Z_2 = A'_2, \quad \nabla A'_2 = B_2, \quad \nabla B_2 = C'_2, \quad \nabla C'_2 = D_2.$$

We may now combine the quantities with suffixes $_1$ and $_2$; thus $B = B_1 + B_2$, &c., and we have

$$\nabla Z = A, \quad \nabla A = B, \quad \nabla B = C, \quad \nabla C = D,$$

where Z, B, and D are pure vectors, Z being the v.-potential of B, which is the actual resultant magnetic force due to currents and magnetism, and B the v.-potential of D. On the other hand, A and C are both scalar and vector, *i.e.*, quaternions, though still A = potential C.

The operator ∇ contains the whole theory of potentials, whether of scalars or vectors. But owing to the remarkably different nature of the effects of ∇ on different functions, it conduces to clearness to distinctly separate the space variation of a scalar, which is easily grasped, from that of a vector, and to instead speak of the curl or the divergence of the latter, as the case may be, and as we have always done hitherto.

(TO BE CONTINUED.)

An Electric Railway for Paris.—A French paper says that the Municipal Council of Paris are considering a project for the construction of an electric railway on the outer boulevards, from La Vilette to the Place Moncey. It is to be 3,077 metres long (about 3,364 yards), and will have nine stations. The permanent way will be erected at a height of 4·75 metres (14ft.) from the road, and the journey will be accomplished in twenty minutes.

ELEMENTARY ELECTRICITY.—XI.

If the hind legs of a frog, together with the portion of the spine from which the lumbar nerves arise, be separated from the body and the legs denuded of their skin, and if a piece of zinc be placed in contact with the nerves while the feet are laid upon a silver plate, no effect will be produced so long as there is no contact between the metals; but if the zinc and silver be made to touch each other, or be joined by a wire of any metal, the legs will immediately contract. According to Matteucci this experiment, in a slightly different form, was shown by Swammerdam to the Grand Duke of Tuscany in 1678. The action was rediscovered in 1786 by Galvani, who considered that it was due to an electric action between the nerves and the muscles. Volta held that the action was due simply to the contact of the dissimilar metals. In 1803 Aldini, a nephew of Galvani, visited London, and showed several experiments in confirmation of his uncle's theory, *i.e.*, that the action was physiological. His experiments showed that muscular contractions could be produced by the action of the nerves upon the muscles without the aid of metals, and subsequently Valli and Matteucci showed that electric currents were produced between nerves and muscles without the intervention of metals. The powerful currents produced by the torpedo, the gymnotus, and other animals confirmed the possibility of producing a current by purely physiological action. An account of modern investigations in this subject would carry us far beyond the limits of these articles. We may, however, mention that by means of a delicate galvanometer, containing 20,000 turns of wire, Du Bois Reymond showed that, if a muscle be cut across, the sides of the fibres are at a higher potential than their cut extremities. One of the greatest hindrances to experiments of this class lies in the great difficulty of obtaining a connection between the animal substance and the terminals of the galvanometer, which may not introduce an electromotive force on account of polarisation, a phenomenon which we shall refer to later on.

Although Galvani rightly maintained the existence of electric currents arising from physiological causes, he nevertheless admitted that in the particular case of the contraction of the frog's legs above referred to the contact of the metals was essential. Many experiments have since shown that electric currents, from whatever cause arising, are capable of producing muscular contractions. If one terminal of a telephone be connected with the sciatic nerve of a recently-killed frog and the other with the gastrocnemius muscle, the frog will leap from his place on calling "froggy" through the telephone.

By means of his condensing electroscope Volta endeavoured to show that electrification is produced by the simple contact of dissimilar metals. By causing a piece of zinc to touch one plate of the condenser and a piece of copper to touch the other, the zinc and copper being made to touch each other, one of the plates became electrified positively and the other negatively. On removing the condensing plate the gold leaves diverged with the charge accumulated in the receiving plate. We shall return to the consideration of the electrification produced by the contact of dissimilar metals shortly.

In 1800 Volta constructed the voltaic pile. It consisted of a series of discs of copper, zinc, and flannel, which were placed one above the other so as to form a pile. The flannel discs were moistened with dilute acid or solution of common salt. Starting with a zinc disc at the bottom, the order in which the plates were arranged was—zinc, flannel, copper, zinc, flannel, &c., the same order being maintained throughout, and the pile terminating with a copper plate. To prevent the liquid running between the copper and zinc plates they were soldered together where they were in contact. On connecting the zinc and copper terminals of the pile a current flowed from the copper to the zinc terminal through the pile.

The "crown of cups" of Volta and the early batteries of Wollaston and others consisted of plates of two dissimilar metals (generally copper and zinc) placed in vessels or cells, containing dilute acid or solution of salt, and connected alter-

Digitized by Google

nately so that the copper of one cell was connected with the zinc of the next, and so on. On connecting the final copper and zinc plates by a wire a current flowed round the circuit as in the voltaic pile. In Wollaston's battery the copper and zinc plates were immersed in cells containing dilute sulphuric acid.

In 1830 Sturgeon introduced the improvement of amalgamating the zinc plates, thus preventing "local action" and preserving the zinc from the action of the acid, except when the current is flowing in the circuit. This improvement obviated the necessity of lifting the plates out of the acid when the battery is not in use.

The followers of Volta maintained that the electric current in the voltaic cell was due entirely to differences of potential produced at the three places of contact of the metals with the acid, and with each other. They held that although in the case of three metals in contact at the same temperature the difference of potential between the metals at the three points of contact balance one another, so that there is no resultant electromotive force round the circuit, yet this is not the case when one of the metals is replaced by a liquid which can act chemically upon one or both of the remaining metals. Thus, supposing the potentials of zinc and of copper to be both lower than than that of sulphuric acid when the metals are in contact with the acid, and in electrical equilibrium, and the potential of zinc to be higher than that of copper when the metals are in equilibrium, the supporters of the voltaic or contact theory maintained that the difference of potential between the sulphuric acid and the zinc necessary for equilibrium was greater than the sum of the differences of potential between the acid and the copper, and between the copper and the zinc, the difference being the resultant electromotive force which urges electricity from the zinc through the acid to the copper and back to the zinc through the metallic junction, when the three substances are connected as in the voltaic cell.

Faraday seems to have seen the necessity for the energy of the electric current being derived from the chemical action going on in the cell, and he consequently regarded this chemical action as the primary source of the electromotive force, as it certainly is of the energy of the current. Faraday supposed the chemical attraction to throw the electrolyte (acid) into a state of electric "polarisation," which state he supposed to be relieved by electric discharge (current) when chemical action actually takes place.

The supporters of the voltaic or contact theory have spent much time in endeavouring to determine at which of the three places of contact in the voltaic cell the chief difference of potential occurs, and many experimentalists have maintained that the electromotive force is due principally or entirely to a difference of potential at the contact of the *dissimilar metals*, and have supposed that the differences of potential at the contacts of the metals and electrolyte are either zero or comparatively small. Several experiments have been cited in support of this view. One of the most recent is due to Sir William Thomson, who showed that when two equal semicircles, one of copper and the other of zinc, are placed with their diameters in contact and a positively electrified "needle" suspended above them, so that, before the plates are made to touch, the needle points in the direction of the common diameter, on making contact between the copper and the zinc the needle turns towards the copper. If a quadrant electrometer be constructed with two quadrants of zinc and the other two (alternate quadrants) of copper, the needle, if positively electrified, will turn so as to enter the copper quadrants, the difference of potential indicated being nearly equal to the electromotive force of a cell consisting of copper and zinc immersed in dilute sulphuric acid. It was at first supposed that these experiments proved a difference of potential to exist between the copper and the zinc sufficient to account for the electromotive force of the voltaic cell. It will be seen, however, that the electrified needle does not move *within the substance* of the copper and zinc, but in the air around the metals, and the experiment therefore only serves to determine the difference of potential of the air near the copper plate, and of that near the zinc plate.

In 1878 Mr. John Brown, of Belfast, experimenting with copper and iron, showed that while the positively electrified needle turned towards the copper quadrants in an atmosphere of air the action was reversed in an atmosphere of sulphuretted hydrogen, the needle turning towards the iron, thus indicating that the gas in the neighbourhood of the iron had a lower potential than that in the neighbourhood of the copper. Hence the motion of the needle is not due to a difference of potential between the metals themselves caused by their contact.

By experiments on the contact electrification of different metals, Volta arranged several of the metals in a series, such that each metal in the series was positive to those below and negative to those above when contact was made between them, while the amount of electrification was greater the farther the metals were separated from each other in the series. It is clear from the experiment of Mr. John Brown, just referred to, that the series can hold good only when the metals are surrounded by certain liquids or gases. Volta's series was determined from experiments in air. Experiments in sulphuretted hydrogen would have led to very different results. The series was the following:—

Zinc,
Lead,
Tin,
Iron,
Copper,
Silver,
Gold.

Platinum and carbon hold a position below gold in the series.

The only reliable method at our command for determining the difference of potentials between two metals in contact is based upon the Peltier effect. When electricity flows from a metal at a high potential to one at a lower potential work is done by the electric forces, and as there is no other source of energy (in a thermo-electric circuit) this work must be derived from heat absorbed at the junction, the absorption constituting the Peltier effect.* Thus, if Q units of electricity pass from one metal to another, the difference of potential being E, a quantity of heat mechanically equivalent to Q E ergs must be absorbed. By measuring the heat absorbed and the quantity of electricity that passes, we can determine E the difference of potential between the two metals. Similarly, if the current passes from a metal at low potential to one at a higher potential, work will be done against the electric forces, and a corresponding amount of heat will be generated. Thus the heat absorbed or developed at a junction of two metals, and constituting the Peltier effect, serves to measure the difference of potential of the two metals. Applying this test to copper and zinc at ordinary temperatures, it appears that the difference of potential is less than the millionth part of the electromotive force developed by a pair of copper and zinc plates immersed in dilute sulphuric acid, and, moreover, the copper is at a higher potential than the zinc. Hence it appears that the difference of potential due to the contact of zinc and copper may safely be neglected in discussing the theory of the voltaic cell.

If we apply the same test in order to determine the difference of potential between either of the metals and the acid in contact with it, we at once meet with a new difficulty, for we can no longer say that when work is done by the electric forces, the only source of energy is the heat absorbed, or that when work is done against the electric forces the whole of the energy expended must appear as heat, inasmuch as a chemical action is going on in contact with the metallic surfaces. If we knew how much heat was being developed or absorbed by this chemical action we might apply the necessary corrections, but though we know what is the whole amount of heat developed (or absorbed) in the battery cell (or the decomposing cell) we do not know what is the exact nature of the action which takes place in the neighbourhood of each metal plate. For example, in the case of a copper and a zinc plate immersed in dilute sulphuric acid we know how much heat is developed when a pound of zinc is dissolved, and the corres-

* The Peltier effect will be discussed when we come to speak of thermo-electricity.

Digitized by Google

ponding amount (about half an ounce) of hydrogen liberated; but when the battery is in action the hydrogen is not liberated at the zinc plate, but in contact with the copper plate, and we do not know what is the condition of the hydrogen while it is travelling from the zinc through the acid to the copper plate. Thus, it may happen that the hydrogen, before it can be liberated as free gas at the surface of the copper plate, must absorb a considerable amount of heat, and this effect would mask the heat developed or absorbed by the electricity in entering the copper plate from the acid; while in the neighbourhood of the zinc plate the heat developed by the chemical action would be in excess of that due to the solution of the zinc and the liberation of *free* hydrogen, by the unknown amount of heat absorbed by the hydrogen when liberated from the copper plate.

(TO BE CONTINUED.)

CORRESPONDENCE.

GAS ENGINES AND THE FUTURE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 19th May Mr. R. E. Crompton asks, "What can the makers of gas engines do for us" (electricians)? and further desires to know whether, with gas at 2s., an engine of 500 horse-power can be worked for 4d. an hour per horse-power, including oil and attendance. Is 4d. a misprint for $\frac{1}{4}$d.? Otherwise I am at a loss to understand the figure at all.

With gas at 1s., one farthing would be a rough approximate estimate of the cost per hour per indicated horse-power of gas, water, oil, and attendance, of an engine of our make indicating 500 horse-power, and giving off about five-sixths of this on the brake.

But why should Mr. Crompton pay so much as even 1s. per 1,000 feet for gas? Let him make gas from anthracite coal, as we are now successfully doing on Dowson's principle, and he shall have an indicated horse-power for, say, $\frac{1}{15}$th of a penny per hour, with anthracite at 10s. per ton—or, say, $1\frac{1}{2}$lb. of anthracite per indicated horse-power per hour.

No one has as yet built a gas engine to indicate so much as 500 horse-power, and to do so an engine with a good many cylinders will, in my judgment, be necessary. Excepting this multiplication of cylinders, I see no difficulty in complying with all Mr. Crompton's requirements, or at least all that seem essential to me. The first cost of a gas plant and gas engine to indicate 500 horse-power need not, if many were required, exceed the first cost of a steam engine and boiler of the class, say, that consumes 30 per cent. more coal than the aforesaid gas engine. The cost of attendance and oil for the gas engine and gas plant would not exceed that required for the steam engine and boilers, and the cost of water being infinitesimal in the case of the gas engines, would form another very great advantage—condensing engines being required to obtain a horse-power for 2lbs. of coal per hour. The space occupied by the steam and gas plants respectively would be about the same.

Against this list of advantages offered by the gas engine plant must be set the fact that it would be comparatively more experimental, and that consequently most people would prefer to pay more money and avoid this risk. But if Mr. Crompton is willing to run this risk, I shall be glad to discuss it with him further in private.—Yours &c.,

Manchester, May 28, 1883. F. W. CROSSLEY.

P.S.—Since writing the above I am informed that Mr. Crompton has corrected the 4d. into $\frac{1}{10}$d. Considering what we say in our prospectus about the Otto engine, this is mysterious in another way, as he is now asking for *almost* what we are commonly affirming. But as my letter has reference mainly to the cheaper gas, I may leave the illuminating gas part of it as it stands, and without further comment. The number of cylinders required to develop the power asked for by Mr. Crompton, while adding to the complexity of the engine, will, I may, perhaps, be allowed to add, give the great steadiness of turning which he also desires.

"INFORMATION WANTED."—MEDICAL MAGNETISM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The editorial appended to the letter addressed to me might answer "Neuralgia," p. 33. However, if he wishes to make a magneticon, let him take two pieces of calico to form a belt to surround the part and fit them with buckles or other fastenings; they should be sewn across in ribs as stays are, in which strips of steel can be inserted. Let the strips of thin steel, say watch spring, be smoothed at the ends, and well magnetised by a magnet. The querist can then insert them in the places prepared for them, after sewing them up in wash leather. If my advice is taken, they would be put together in pairs with N and S poles in contact. They would then retain their magnetism a long while and exert no external action whatever, or slips of thin whalebone may be substituted with advantage. The essential point is to line the belt with a slip of good rough flannel, which can be removed at intervals and replaced with new, not washed and put back.

I used to think the magnetic appliances mere inert affairs, having possibly a use in stimulating the imagination (I know a person who says he keeps off rheumatism by always carrying a fresh raw potato in his pocket), but some of the medical gentlemen have brought forward evidence to prove that the magnets do really act upon the body, and the result is to convince me they may possibly do mischief. They cannot really do anything except disturb the circulation of the blood; they cannot assist it because they cannot possibly put any energy into the body. But, as the blood is magnetic, it is quite possible for an external magnet to arrest its motion and cause a congestion at the polar points; and in what way this, the only conceivable real action, can be beneficial I cannot imagine.

But anything whatever in which a person believes will unquestionably do good. By stimulating hopeful expectation it will assist the action of the liver (just as, conversely, a gloomy, apprehensive state of mind will derange its action), and thus benefit will result; for rheumatism and neuralgia are undoubtedly traceable to imperfect action of the liver, and consequent accumulation of waste products which ought to have been removed. But whatever my ideas as to the medical "uses of the imagination" I cannot possibly, as a man of science, actually support a physical explanation which is obviously incorrect. Such is the case with the assumed effects of magnets, which have always been the favourite mine for perpetual-motion mongers and quacks of all sorts; simply because magnets seem, to those who do not understand the truth, to possess an inexhaustible power of doing work, whereas, as a matter of simple fact, they can do no work at all unless an external supply of energy is provided.—Yours, &c., J. T. SPRAGUE.

EARTHQUAKES AND THEIR ORIGIN.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have read with great interest your Zante correspondent's letter, published in *The Electrician* of April 28, and am happy to be able to confirm from personal observations much of what he states in it.

Crete, like nearly all the islands in the Eastern Mediterranean, is subject from time to time to earthquake shocks, more or less violent, and although since the catastrophe of 1856 (when nearly every village on the island was destroyed and the town of Candia reduced to ruins) there have been no really serious shocks, we are still frequently reminded of what may possibly yet be in store for us, despite the generally believed theory that the volcano which opened during the earthquake of 1856 in the Bay of Santorin (an island about 50 miles to the northwards of Candia) has acted, and will continue to act, as a safety valve for this and other neighbouring islands. Like Mr. Forster, I have always hoped to have the chance of testing a cable at the moment when an earthquake is actually going on, but have not succeeded as yet. I have, however, frequently observed that for some hours before and after a shock there have invariably been magnetic disturbances on one or other of the cables (but principally on the Candia-Zante section). These disturb-

Digitized by Google

ances show themselves by difficulties in working or (if I have been testing about that time) by violent vibrations on my usually very steady astatic galvanometer.

On April 2nd, I tested the Candia-Canea section at the same hour that Mr. Forster was testing that from Zante to Canea, and I find the following observations in my notebook:—

"Candia-Canea section. Insulation readings extremely unsteady. Light flying off scale every second. When line to earth at Canea vibrations still more violent. Galvanometer heavily shunted, but unable to get copper resistance at all."

I had also tested the Candia-Alexandria cable an hour before, and the insulation deflections were unusually unsteady and vibratory.

Shortly after midday we had a slight, undulatory shock of earthquake. This is the more unusual as it is the first case I remember, since my arrival in 1879, of Zante and Crete suffering from shocks on the same day. Candia seems to lay along a *separate* line of seismic force, as very frequently we feel shocks here which are not sensible in towns and villages twenty miles to the west and east of us, and whenever there has been a severe "quake" in Crete this town has always suffered the most. There seems to be some, as yet unsolved, relation between the lines of magnetic and seismic force.

Surely some of your readers who are stationed along the West Coast of South America, where earthquakes are the rule and not the exception, might furnish some interesting data on the subject.—Yours, &c.,

GEO. ALMOND, Supt. E. T. Company,
Candia, Crete, May 6, 1883.

ELECTRIC LIGHT FOR NOTHING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Following up the very practical letter of "W. M." in your last issue, I should like to second that writer's remarks as to the wisdom of working for nothing. It has been my fortune or misfortune to have been not unfrequently accused to my face of having taken contracts at an unremunerative rate for the purpose of securing the market, and I have been accused of cutting the throat of the trade by so doing. I take this opportunity of stating that although my company has on its books probably more and larger contracts than any other single company, yet no single contract has yet been undertaken from which we do not secure a fair commercial profit. I would also add that I have frequently come across cases of large and important companies having offered to put in an installation free gratis, and experience is proving to me how suicidal is this policy, for its result is that of retarding sound business by encouraging intending purchasers to wait until they, too, like their more successful neighbour, get the light for nothing. Surely we may now fairly claim that electric lighting has got out of its long lived infancy, and is past the stage of mere experimentalism, and that this unhealthy practice of giving away is no longer needed.

Therefore I would urge all companies to buckle to in right earnest, and surely we shall find work in abundance far exceeding the capabilities of the united electrical industry of Great Britain. As a misapprehension has arisen as to who is the patentee of the new storage batteries manufactured by this company, I take this opportunity of explaining that the inventor is Professor Charles Forbes.—Yours, &c.,

J. EVANS JACKSON.
Electric Carbon, Storage, &c., Co., Leith, May 29, 1883.

AYRTON AND PERRY'S MOTOR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: At the last Cantor lecture this season I exhibited to the Society of Arts a compact "half-horse" motor which Professors Ayrton and Perry had been good enough to lend, applying to it an E.M.F. of about 60 volts, from 29 Faure-Sellon-Volckmar cells; but I was able to stop the motor with one hand. This apparent failure of the machine was due to a resistance coil which had been added to it in order to prevent its racing itself to pieces when it was doing no work. By some oversight I had not been informed of the existence of this resistance, and consequently I did not remove it when testing the power of the machine. Under these circumstances it is not surprising that it refused to work as well as the De Meritens motor, which had no such artificial obstruction between it and the battery. I think it only fair to the patentees of the motor to make this explanation of an occurrence which they fear might otherwise have a damaging effect.—Yours, &c.,

OLIVER J. LODGE.
University College, Liverpool, 30th May, 1883.

INCANDESCENT LAMPS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: At page 26 of your issue of 26th inst. you mention an invention of Mr. C. F. Brush for preserving the filaments of incandescent lamps from "molecular bombardment."

I beg to inform you that the invention in question was anticipated by Mr. J. S. Beeman by his patent, No. 3279, of 11th July, 1882, under which he claims the use of mica, talc, glass, or other non-conducting material, as a possible support to the carbon filaments, and as a reflector and shield.

The specification describes that the mica support will act as a non-conducting diaphragm to arrest the deposit of carbon particles on either side or on various parts of the filament.

The patent in question is the property of this company.—Yours, &c.,

GEO. OFFOR.
The Consolidated Electric Company, 110, Cannon-street, London, E.C., 28th May, 1883.

THERMOPILES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any of your readers inform me of the proportions of zinc and antimony used in making the alloy for the negative elements of Clamond's thermopile?—Yours, &c.,

C. D. S.
45, Savile Mount, Halifax.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The letter of "T. L. P." in your last week's issue is a contribution in the right direction, and shows that good earth connections can be got for lightning conductors, where there is the skill to direct operations, and to determine accurately the electrical condition of the same. It would, however, be of additional value if he were to inform your readers whether he made his tests in the same manner as described for the General Assembly Hall, Edinburgh, viz., the having a testing wire temporarily connected with the point, so as to test the whole, conductor and earth. For the help of those who may want to test conductors, and who are away from verbal instruction, could he say in a comprehensive manner what battery power he employed, kind of instrument used for testing, say differential or Wheatstone bridge method of making earth for the test connections, &c., together with what assistance he needed. This would in some way compensate for the absence of any such matter in the Lightning Rod Conference Report, a fact much to be regretted, as in spite of constantly urging the value of good earth, and the necessity for tests, there is no word upon the "how" of testing, or a line to say whether 10, 20, or 50 ohms are safe margins. As doctors differ, so may electricians, and whilst one might insist upon a single ohm, others might, like Captain Bucknill, consider nearly a 1,000 ohm joint safe. It would be of much interest if at the close if this correspondence, your own views could be stated in an article.—Yours &c.,

May 29, 1883. GOOD EARTH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I, through your columns, ask "T. L. P." to give me an insight into the manner of testing "earths" of as low a resistance as he describes, and the instruments he would use to get so accurate a result. Hoping he will give me the information I require.—Yours, &c., STUDENS.

ELECTRICITY AS A MOTIVE POWER.*

BY PROFESSOR GEORGE FORBES.

(CONCLUDED FROM PAGE 43.)

Having now spoken of the applications of electricity to stationary engines, let us see what has been done, and what can be done, with respect to locomotives. There are two ways in which this application has been made. First, by storing the electricity in accumulators, and putting the accumulators in a tramcar, a boat, or a tricycle; and second, by deriving the current from a wire or other conductor placed along the line. The experiments made upon the first plan are very interesting, but their practical value is limited, owing to the weight and expense of the accumulators. I think that it would be far more economical to use compressed air engines. Ever since 1875, when I examined the compressed air tramcar of Scott Moncrieff, which ran so successfully in Glasgow, I have felt sure that this must become eventually the motive power for tramcars, and I have not yet seen anything to lead me to alter my opinion.

What has been done in the second way of proceeding? We will see that considerable progress has been made. At the Berlin Exhibition in 1879, Messrs. Siemens and Halske drove a train of a few carriages round a circular tramway, the gauge being three-quarters of a metre. In April, 1881, the same firm constructed the Lichterfelde and Berlin electrical railway, which is two miles long. One of the carriages of this railway was shown at the Paris Exhibition of 1881. The current is passed through the rails, which are insulated. It is then taken up by the wheels, and so passed through the motor. The motor turns at a very rapid rate, but it is geared to the wheels of the carriage by belting of wire-rope, which reduces the speed of revolution. The carriage has the appearance of an ordinary tramway-car, and the machinery is invisible. It was expected that snow might prove troublesome in such a system where the current is passed through the rails, but the winter of 1881-82 was so mild as to give no trouble. I have not heard whether any difficulty presented itself during the past winter. At the Paris Electrical Exhibition a somewhat similar car was used, but Messrs. Siemens were not allowed to pass the current through the rails, on account of the danger to horses, &c.; hence they were obliged to carry conductors, consisting of split tubes, on telegraph poles, and a small carriage fitting into the tubes made electrical contact with the motor on the car. Another electric railway has now been completed by the same firm, between Charlottenburg and Spandauer Bock. In this case also, a contact carriage is used, as at Paris. This line is three and a half kilometres long; two and a-half kilometres are level, but this line is specially interesting from the fact that a whole kilometre is on the considerable incline of 1 in 28. Messrs. Siemens have also applied the same principle to haulage in mines. A small electrical locomotive is used in a mine near Dresden to drive eight corves loaded with coal. Finally we have the electrical tramcar running on the Portrush line, in the North of Ireland, but this has been so well described in this room, and so recently, that I need only mention it.

It has always seemed to me that the principal advantage which would be gained by using electricity as a motive power for railway trains, lies in the great facility with which motive power could be applied to every wheel of the whole train. Captain Douglas Galton, in the concluding paragraph of his report on experiments, conducted by himself and Mr. Westinghouse, on continuous brakes, says :—The advantage which thus evidently ensues from utilising the adhesion of every wheel of a train, suggests the further consideration as to whether it would not be a more scientific arrangement, as well as being more economical in regard to the permanent way of railways, to utilise the adhesion of every wheel of a train for causing the train to move forwards, instead of depending for the moving force upon the adhesion of one heavy vehicle alone, viz., the locomotive."

Certainly there can be no doubt that it would save the permanent way from tear and wear, and the passengers from the shocks which are so unpleasant, but it is only by means of electricity that the proposition is practical; moreover, the movable parts of a locomotive are not perfectly balanced, and this limits the speed at which it can go. With an electrical motor the balance is perfect. By utilising a motor on every wheel you could go safely round curves at far greater speed. I feel sure that in this way it would be safe for trains to go at double the speed they do at present, and I hope to live to travel from London to Edinburgh in three and a half hours, smoothly, and without jolting. Furthermore, a train, instead of taking several minutes to get up full speed, could do so in a few seconds. This follows from the same reasoning as is applied to continuous brakes. Lastly, if there were power enough, a train could go up a steep hill instead of being confined, as practically they are, to an inclination of 1 in 80. In a district with heavy goods traffic, this might be a great advantage.

These considerations appear to me to be so important, that I must pause a while to make them clear.

First.—As to getting up speed quickly. With an ordinary train, weighing ten times as much as the engine, the theoretical minimum of time required to get up a speed of thirty miles an hour is one minute, however powerful the engine may be. The reason is that the wheels would slip if the motion were accelerated more rapidly. But if power were applied to every wheel, it would have a speed of 30 miles an hour in six seconds, and with no more jerk than is now felt when a continuous brake is applied.

Second.—As to the going up hill. The same advantage here is gained as would be gained by continuous brakes. An ordinary train, when the lines are in an average condition, slips down an incline of 1 in 50, when the locomotive alone is braked. You all remember the sad accident the other day in the Rocky Mountains from this cause. But when all the wheels are braked, the train rests on an incline of 1 in 5. So also, if we had the power, we could ascend an incline of 1 in 5 by electrical motors.

Third.—As to advantage to permanent way. The engine does not give a steady pull at all times to all parts of the train. In fact, in going round a curve, part of the engine's power is used up in trying to pull part of the train off the lines. With power applied to all the wheels, this would not be so. Moreover, the enormous weight of the locomotive, imperfectly balanced, which is the chief source of mischief, would be done away with.

Fourth.—As to cost. The cost of making an ordinary railway line with tunnels, embankments, bridges, viaducts, &c., in England, may be taken at £15,000 a mile; but if it goes up inclines instead of having expensive engineering works, the cost will be the same as making it on a level, *i.e.*, £5,000; and hence, on a goods line, the cost of construction might be reduced to one-third. This original outlay is a far more serious matter than the working expenses of a railway (of which the cost of the traffic is 26 per cent.); so that, even if by using electricity you increased your working expenses you might still be making a great saving on the whole. On fast passenger trains the power to drive your trains at twice the speed would counterbalance any small loss of economy.

There are many cases where such an application of motive power would be peculiarly satisfactory. The most important of these is the Underground Railway in our city. It is now universally admitted that steam locomotives vitiate the air to an intolerable extent. If motive power were used electrically, this evil would be avoided. Moreover, a line like this, which is almost totally underground, and is comparatively unaffected by snow or rain, possesses exceptional advantages for electrical insulation. But the system which I have advocated would introduce special advantages to this line. What are the conditions of working? The distance between stations is so short that a great deal of time is wasted in getting up speed and stopping the trains. The latter evil, it is true, has been reduced to a minimum by the adoption of continuous brakes; but you will understand how much speed is limited by the former consideration, when I tell you that an ordinary train cannot get up a speed of thirty miles an hour until it has passed over a quarter of a mile, just about the distance between some of the stations. If the system I propose were adopted of applying motive power to every wheel, the same speed would be attained in forty-four yards.

The Channel Tunnel, when completed, will be specially favourable for the insulation of conductors. But the system which I recommend could not be adopted, as the great advantage of the tunnel is that the same waggons will go right through without any transference of goods. In this case, if electricity be used as the motive power, it would be necessary to use it to drive a heavy locomotive.

I think I have now said enough to prove that a great deal has already been done, and that we may reasonably expect a great deal more to be done in the use of electricity as a motive power. Water-power has been usefully employed in various installations, to obtain electricity, and the current has been successfully conveyed several miles, to be reconverted into motive power with great economy, and electric railways have been successfully and economically worked by electricity. I have not thought it right in this lecture to indulge in Utopian dreams of what may be done in the future, however pleasant such an exercise of the imagination might have been. I have thought it to be more useful to look at the matter from a practical point of view, and to estimate our present position with respect to this force, and to indicate the steps which our past experience would warrant us in taking in the immediate future. I should like to see a larger number of our wealthy compatriots experimentalising in this field, so as to keep our country in the front rank of the applications of electricity, as she always has been in those of steam. But we must go on step by step—learning from every fresh experiment, and utilising experience for further advances.

PROF. HUGHES ON MAGNETISM.

The invention of the telephone gave rise to an unusual amount of attention being concentrated on magnetic phenomena. More recently their application to the production of electrical currents for illuminating purposes has increased their practical significance, and rendered a trustworthy explanation, or serviceable working theory, much sought after. Two of, perhaps, the most startling, as well as most interesting, papers ever read before the Society of Telegraph Engineers and of Electricians have been devoted to this subject by men whose reputation in the field of experimental scientific research justifies the belief that their conclusions have, at all events set the theory of magnetism on a sounder basis than it had previously enjoyed. We refer, of course, to Mr. Stroh's remarkable illustrations thirteen months ago, and to Professor Hughes's experiments last Thursday week. With two such indefatigable and adroit inquirers as these busily interrogating magnetism as to what it really is, a true answer cannot long be withheld.

Not that anybody expects a very complete answer to the question, though we may get one that is true so far as it goes. But it is one thing to be content with an approximate answer, and another to treat all such questions as idle. What is electricity? what is magnetism? are questions which are often contemptuously set aside as unprofitable, we suspect, only because the answers have not been easily forthcoming. In the absence of precise knowledge we make believe to be satisfied with fanciful theories—theories which have had to shift and be remoulded with every fresh extension of our acquaintance with phenomena. If a history of theories ever comes to be written, it will be one long satire on the rashness and vanity of human speculation; consequently, it will probably never be written, for the only people specially concerned would find it very humiliating reading. Theories relating to the unknown have a chance of living just so long as the known facts are in accord with them; fresh theories have then to be propounded, which again receive their quietus with the last new discovery. All this is perfectly natural and quite inevitable; only what would strike the historian as exceedingly odd is that the course of science, which is nothing if not exact, is just as thickly strewn with exploded theories—superstitions one may almost call them—as metaphysics and theology. The substantial service rendered by men like Bjerkness, Stroh, and Hughes, is that they add immensely to the sum of our knowledge of facts. If they do not tell us what the thing is, they show us more precisely what it does, or at all events what it seems to do; and they sweep away a host of conflicting and confusing conjectures which have ceased to be of any practical utility.

This last, in the opinion, we think, of most of his audience was what Professor Hughes succeeded in doing the other evening. Popular text books would have to be remodelled under the new light thrown on the phenomena of magnetism. This was the general impression created by a series of experimental demonstrations, the novelty of which was undeniable. It does not follow, however, that the theory advanced by the ingenious professor is itself a final one. It fits the new facts, and, to use his own words, "in every portion allows at least experimental evidences of its probable truth." It is, one may cordially admit, a more consistent theory than any yet advanced, and, granting that theorising was necessary for the occasion, a highly valuable addition to the list. But it is possible, just possible, the facts may fit equally well, or even better, with some other theory still to be advanced. Microphonic phenomena are none the less instructive because nobody can agree in explaining them; and these novel discoveries relating to the behaviour of magnetism will bear fruit all the same, whether the discoverer's explanation be the right one or not.

It is natural we should couple the two papers together, one by Mr. Stroh and the other from Professor Hughes; but they differed very greatly in their treatment of the subject. The first, although following up a consistent line of investigation, which in itself implied a definite perception of what was likely to happen, scarcely ventured on the domain of theory at all—thus and thus the phenomena are shown to act; I do not know the cause; I will not hazard a guess. The other, though setting to work in much the same spirit felt constrained, apparently as a matter of conscience, to formulate a theory to account for them, lest, perhaps, people should doubt the facts. We need not share, though we may sympathise with these apprehensions. Many people will repeat Professor Hughes's experiments; they will, in all probability, furnish an absorbing subject of experimental verification for some time to come. His discoveries will be confirmed, and fresh ones probably contributed; but it will greatly surprise us if the explanation from all quarters tallies with that of the experimenter-in-chief. If it is alleged that you must have a theory, a working theory, for every-day use, the reply is, if you must, you must, but you will be very apt to go wrong upon it. Only the other day two eminent professors were seen inquiring what was the most efficient form of magnetic motor. Theory, of which they are credited with a quite adequate stock, apparently did not supply the answer; they had to test a number of motors of varying sizes and weights in order to discover their relative powers. Any working man could do that without a theory. Perhaps Pro-

Digitized by Google

fessor Hughes would retort that this only proves the necessity for some guiding principle on which we may safely make our calculations. It certainly does prove the desirability, but the necessity is not so self-evident; and, at all events, there is no necessity for hurry. Accumulate facts by all means, and from the recesses of nature as far as you can probe them; but the only durable theory in the long run will be that which formulates itself when all the phenomena are known.

It would be premature to offer any observation in the way of serious criticism on Professor Hughes's theory. But as regards the facts, it will be noticed that he has paid a great deal of attention to what takes place inside the magnet, previous researches having dealt mostly with what takes place outside it. Perhaps the peculiar merit of his experiments, the most important of them, was that they brought into greater prominence the action of the earth's external magnetism upon magnetic metals. It probably is the case that the molecules of soft iron are freer to move than those of hard steel, but it still remains to be answered why if they are freer to move they are not also freer to stop where they have been moved to. Why should they move to their old position instead of stopping where the earth's magnetism transiently directed them? Further, there were certain magnetic actions so like electrical phenomena brought out in the course of his paper that the reader is surprised Professor Hughes did not make more of them. Magnetism and electricity are so nearly related that every point of identity deserves to be carefully noted, tested, and demonstrated with the keenest interest. No one could fail to see that Professor Hughes's mallet and his torsion appliances often did duty for an electrical current.

THE CAUSE OF EVIDENT MAGNETISM IN IRON, STEEL, AND OTHER MAGNETIC METALS.*

The extreme sensitiveness of the induction balance to all molecular changes in the structure of metals was remarked in my first paper on this subject to the Royal Society;† and in the case of iron and steel it is most remarkable, as the addition or subtraction of $\frac{1}{300000}$ part, or the addition of the smallest iron filing to an already large balanced mass of iron, is at once rendered evident and measurable.

Possessing such an invaluable instrument of research, I was desirous of investigating the molecular construction of iron and steel, but at once I met with a difficulty, viz., that magnetism itself completely changed the character of any piece of iron under investigation; consequently, finding no help or explanation of the effects produced from any accepted theories of magnetism, I was forced to investigate, by means of the induction balance, the whole question of magnetism as existing in the interior of a magnet, and to determine the particular structure for each case, such as neutrality and polarity.

In a recent paper to the Royal Society, upon the theory of magnetism,‡ I described the use of and demonstrations obtained by the induction balance. In this paper I propose to confine myself to demonstrations that can be repeated without it, and whose effects can be observed by the aid of ordinary magnetic direction needles.

That magnetism is of a molecular nature has long been accepted, for it is evident that, no matter how much we divide a magnet, we still have its two poles in each separate portion, consequently we can easily imagine this division carried so far, that we should at last arrive at the molecule itself possessing its two distinctive poles, consequently all theories of magnetism attempt some explanation of the cause of this molecular polarity, and the reason for apparent neutrality in a mass of iron.

Coulomb and Poisson assume that each molecule is a sphere containing two distinct magnetic fluids, which in the state of neutrality are mixed together, but when polarised are separated from each other at opposite sides; and, in order to explain why these fluids are kept apart as in a permanent magnet, they had to assume, again, that each molecule contained a peculiar coercive force, whose functions were to prevent any change or mixing of these fluids when separated.

There is not one experimental evidence to prove the truth of this assumption; and as regards coercive force, we have direct experimental proof opposing this view, as we know that molecular rigidity or hardness, as in tempered steel, and molecular freedom or softness, as in soft iron, fulfil all the conditions of this assumed coercive force.

Ampère's theory, based upon the analogy of electric currents, supposes elementary currents flowing around each molecule, and that in the neutral state these molecules are arranged haphazard in all directions, but that magnetisation consists in arranging them symmetrically.

The objections to Ampère's theory are numerous. 1st. We have no knowledge or experimental proof of any elementary electric currents continually flowing without any expenditure of energy. 2nd. If we admit the assumption of electric currents around each molecule, the molecule itself would then be electro-magnetic, and the question still remains, What is polarity? Have the supposed electric currents separated the two assumed magnetic fluids contained in the molecule, as in Poisson's theory? or are the electric currents themselves magnetic, independent of the iron molecule?

In order to produce the supposed heterogeneous arrangement of neutrality, Ampère's currents would have either to change their position upon the molecule, and have no fixed axis of rotation, or else the molecule, with its currents and polarities, would rotate, and thus be acting in accordance with the theory of De la Rive. 3rd. This theory does not explain why (as in the case of soft iron) polarity should disappear whenever the exciting cause is removed, as in the case of transient magnetisation. It would thus require a coercive force in iron to cause exactly one-half of the molecules to instantly reverse their direction, in order to pass from apparent external polarity to that of neutrality.

The influence of mechanical vibrations and stress upon iron in facilitating or discharging its magnetism, as proved by Matteucci, 1847, in addition to the discovery by Page, 1837, of a molecular movement taking place in iron during its magnetisation, producing audible sounds, and the discovery by Dr. Joule, 1842, of the elongation of iron when magnetised, led De la Rive, in his remarkable "Treatise on Electricity," 1853, to give his theoretical views upon magnetism in the following remarkable words:—

"The whole of the magnetic molecular phenomena that we have been studying lead us to believe that the magnetisation of a body is due to a particular arrangement of its molecules, originally endowed with magnetic virtue, but which in the natural state are so arranged that the magnetism of the body that they constitute is not apparent. Magnetism would, therefore, consist in disturbing this state of equilibrium, or in giving to the particles an arrangement that makes manifest the property with which they are endowed, and not in developing it in them. The coercitive force should be the resistance of the molecules to change their relative positions."

Wiedermann, in 1861, gives a theory in which he admits the fluids of Poisson, or the elementary currents of Ampère, as the cause of polarity of the molecule, but belives that the molecules are turned in a general direction in the case of polarity, and that in neutrality, like Ampère's, the magnetic axes of the molecules are turned in all directions.

Maxwell, in his remarkable treatise on "Electricity and Magnetism," 1881, page 77, gives the following *résumé* of Weber's theory:—

"Weber's theory differs from Poisson's, in assuming that the molecules of the iron are always magnets, even before the application of the magnetising force, but that in ordinary iron the magnetic axes of the molecules are turned indifferently in every direction, so that the iron, as a whole, exhibits no magnetic properties." And again, page 429, Maxwell says he agrees with Weber's views, and that neutrality, or unmagnetised iron, has the axes of its molecules placed indifferently in all directions, and that the act of magnetisation consists in turning all the molecules so that their axes are either rendered all parallel to one direction, or at least deflected in that direction.

I have quoted these several theories which admit of the inherent polarity of the molecule, and in that respect they entirely agree with my own; but the induction balance at once shows that they are erroneous in the most important part, for my researches have proved that neutrality is perfectly symmetrical, that there is no case of neutrality where the axes of the molecules are turned indifferently in all directions, and that we cannot obtain perfect neutrality except when the molecules form a complete closed circuit of attraction.

I believe that a true theory of magnetism should admit of complete demonstration, that it should present no anomalies, and that all the known effects should at once be explained by it.

From numerous researches I have gradually formed a theory of magnetism entirely based upon experimental results, and these have led me to the following conclusions :—

1. That each molecule of a piece of iron, steel, or other magnetic metal is a separate and independent magnet, having its two poles and distribution of magnetic polarity exactly the same as its total evident magnetism when noticed upon a steel bar-magnet.

2. That each molecule, or its polarity, can be rotated in either direction upon its axis by torsion, stress, or by physical forces, such as magnetism and electricity.

3. That the inherent polarity or magnetism of each molecule is a constant quantity like gravity; that it can neither be augmented nor destroyed.

4. That when we have external neutrality, or no apparent magnetism, the molecules, or their polarities, arrange themselves so as to satisfy their mutual attraction by the shortest path, and thus form a complete closed circuit of attraction.

5. That when magnetism becomes evident, the molecules or their polarities have all rotated symmetrically in a given direction, producing a north pole if rotated in that direction as regards the piece of steel, or a south pole if rotated in the opposite direction. Also, that in evident magnetism, we have still a symmetrical arrangement, but one whose circles of attraction are not completed except through an external armature joining both poles.

6. That we have permanent magnetism when the molecular rigidity, as in tempered steel, retains them in a given direction, and transient magnetism whenever the molecules rotate in comparative freedom, as in soft iron.

Experimental Evidences.

In the above theory the coercive force of Poisson is replaced by molecular rigidity and freedom; and as the effects of mechanical vibrations, torsion, and stress upon the apparent destruction and facilitation of magnetism is well known, I will, before demonstrating the more serious parts of the theory, cite a few experiments to prove that molecular rigidity fulfils all the requirements of an assumed coercive force.

The influence of vibrations, torsion, or stress of any kind upon a magnetised steel or iron rod may be seen by striking with a wooden mallet rods of hard and soft steel, also hard and soft iron previously magnetised to a known degree. The tempered steel, owing to its molecular rigidity, will lose but 5 per cent., the soft steel 60, hard iron 50, and soft Swedish iron 99 per cent. of its magnetism, the amount of loss depending not so much upon whether the metal be steel or iron, as upon its degree of hardness and softness; and as hard steel requires far more power to magnetise it to the same force than iron, it is possible to imagine a steel so hard that its molecules could not rotate, and that, consequently, no magnetism could be manifested from a given inducing cause, whilst a perfectly soft iron would give the maximum effect and instantly return to its previous state. From this we might, in error, suppose that soft Swedish iron could not retain its magnetism, and that its natural state would be zero, or neutrality. The apparent disappearance of magnetism, however, is here due to the extreme freedom of motion of its molecules allowing them at once to follow the comparatively feeble directing force of the earth's magnetism. We can demonstrate this by feebly magnetising a rod of soft iron held vertically, so that its north pole is at the lower portion. Upon removing the inducing magnet, or electro-magnetic coil, we find that the rod retains a powerful north polarity, but if magnetised in a contrary sense then we have only *traces* of magnetism left upon the withdrawal of the inducing cause. To succeed in this experiment, as in all others where soft iron is mentioned, we should use the best Swedish charcoal iron, thoroughly annealed at high temperature.

We find, again, that rods of steel or iron will lose far less magnetism when vibrated in the magnetic dip, or vertically, when their north poles are at the lowest extremity, than when horizontal, or still less than when their poles are contrary to those of the earth's field, and also that they will acquire their maximum magnetism from a given exciting cause when held vertically as described, and the molecules allowed greater freedom of motion to obey the directing influence by vibrations, torsion, stress, or blows upon the iron. Any influence that would tend to give greater freedom of motion, such as heat or mechanical trepidations, gives a far higher magnetic force to the iron than could be obtained without these aids.

In order to render visible the effects of motion upon magnetism, we may take two glass tubes, or ordinary phials, of any length or diameter, say 10 centimetres in length by 2 centimetres in diameter. If we now put iron filings in these tubes, leaving about one-third vacant, so as to allow complete freedom in the filings when shaken, we find that each tube, when magnetised, retains an equal amount of residual magnetism, and that this all disappears upon slightly shaking the tube. We are thus imitating the effects of vibration. But if in one of these tubes we pour melted resin (in fact, any slightly viscous liquid, such as petroleum, suffices), we then render these filings more rigid, and then we can no longer produce by shaking the disappearance of its residual magnetism. In pouring in petroleum we have apparently been introducing a strong coercitive force, but we know that it can only have the mechanical effect of rendering the iron filings less free to turn, and so comparatively rigid. If we desire to see the effect of torsion, we have only to shake the filings so that when the tube is held horizontally the vacant space is above, and rotate it slightly (but without shaking) about a horizontal axis. Its remaining magnetism instantly disappears upon rotation, although we evidently have not changed the longitudinal position of its particles. A similar effect takes places upon a soft iron rod, for if we magnetise it and observe its remaining magnetism, we find that, upon giving a slight torsion to this wire, its remaining magnetism instantly disappears—a similar effect to that in the rotating tube of iron filings. But if the iron is rendered more rigid by hammering, or steel rendered hard and rigid by tempering, torsions or vibrations have but little effect, as in the case of the filings rendered rigid as above mentioned. Thus we have no longer need of an assumed mysterious coercive force to account for the retention of magnetism, for once knowing the mechanical qualities of iron and steel, and their degree of molecular rigidity or hardness, we can at once predict their retentive magnetic powers.*

Rotation of Inherent Polarised Molecules.

Torsion, as well as mechanical vibrations, has, as we have seen, a powerful influence in aiding the molecules to overcome their inertia, and thus aid them to rotate in the direction of the inducing influence; and we may thus polarise strongly a flat soft iron rod by simply bending or vibrating it when held vertically, and if we measure the magnetic force obtained we shall notice that the force is strictly relative to the degree of softness of the iron. Thus, with hard steel we should obtain only *traces* of polarisation, whilst with extremely pure soft Swedish iron we obtain the maximum of force. The bar of iron or steel, being held in the earth's magnetic field, of infinite size compared with the bar, and infinitely homogeneous, cannot deflect or weaken its surrounding field. Its lower portion being north, apparently strengthens it by its reaction, whilst its upper, south, apparently weakens the field; but, as Maxwell has shown, "the two poles of each molecule are equal and opposite, consequently the sum of each molecule and the whole mass must be zero."

We have a far greater induced polarity in iron or steel when the iron is in thin bars or small wires, and this we should expect, as the external molecules rotate directly under the influence of the earth's magnetism, whilst those forming the interior of the bar either rotate feebly, or, as in the case of very thick bars, actually act as an armature, preventing, by their influence, free rotation of the exterior molecules.

Thus, as the sum of the two and equal polarities in a bar of iron is zero, it is evident that its polarity must be inherent. I have some remarkably pure soft Swedish iron wire, one millimetre in diameter, and as its inherent polar force seemed great when held vertically in the earth's magnetic field, I measured in the induction balance this force compared with a similar column of the magnetic atmosphere which it displaced. The inherent polarity of this wire, simply rendered evident by the earth's magnetism, was 15,000 times greater than the column it displaced.

We cannot, either by induction, conduction, or concentration, produce a greater force in another body of similar displacement or size, otherwise we could easily create power from a feeble source. Thus, the enormously greater magnetic power observed in iron than the same column of air which it displaces must be due to the *inherent* polarity of its molecules.

Amongst numerous bars of iron upon which I have experimented, one of ordinary hoop-iron, 2 centimetres wide, 40 centimetres long, and 1¼ millimetre thick, not softened, possesses sufficient molecular rigidity to be apparently uninfluenced by earth's magnetism. When this rod is rendered neutral, we have but feeble polarity—mere traces when it is held vertically under the earth's magnetic influence; but if we apply a few successive torsions or vibrations to it when thus held, we have at once several thousand times greater polarity than before. Now, if iron had the power of deflecting or concentrating the earth's magnetism upon itself, it should not require the mechanical aid to molecular rotation given to it by these torsions or vibrations. Thus we are forced to conclude at least the existence of the inherent

* "On the Molecular Rigidity of Tempered Steel," by Professor D. E. Hughes, F.R.S.—*Proceedings Institution of Mechanical Engineers*, pages 72—79, January, 1883.

Digitized by Google

polarity of the molecules; and, if we admit this, we must also, as a necessary consequence, admit the rotation of these molecules, else we cannot explain why mechanical vibrations allowing freedom of motion should always produce the polarity in accordance with the directing cause. I have already shown that torsion and vibrations *per se* are apparently destructive of magnetism; consequently, in this case Poisson's two fluids and Ampère's parallel currents should, according to their theory, be mixed or heterogeneous, whilst according to the views I am sustaining the polarised molecules should obey, as compass needles, any magnetic directing cause whenever sufficient molecular freedom of motion allows free rotation.

The inherent polarity of iron may again be observed by drawing a flat rod of soft iron over one or both poles of a permanent magnet. This rod will then be powerfully magnetised, its remaining magnetism, when separated from the magnet, being sufficiently powerful to strongly deflect a suspended direction needle. A few slight torsions or vibrations will then completely discharge it. Now, suppose this operation repeated successively many thousand times, if there was no inherent polarity we should have gradually drawn all the polarity out of the magnet, and discharged it into the atmosphere. Nothing of the kind takes place. The molecules of the iron are simply rotated each time, and the only energy in work expended or lost comes from the arm of the experimenter, and the energy required would be strictly in accordance with the molecular freedom, or softness and hardness of the iron and steel; thus, whilst soft iron could be easily polarised and discharged by mechanical torsions, hard-tempered steel would require a far greater amount.

Dr. Warren De La Rue, F.R.S., kindly aided me in this part of the research by passing a current from his well-known chloride of silver battery through iron and steel wires. A condenser of 42·8 microfarad capacity, charged by 3·360 cells, was used. We passed this enormous electric charge longitudinally through the wires, and observations were made as to whether any change whatever was produced in their quality or inherent polarity, the result being that these wires gave exactly the same magnetic polarity from a given directing or inducing cause as before, being similar in nature and degree; consequently, this enormous electric force had not changed or destroyed the original inherent polarity.

If the molecules possess inherent polarity and rotate upon their axes, similar to a series of compass needles having a slight degree of frictional rigidity, then, upon passing one pole of a magnet above them, they would turn symmetrically in one direction, and drawing the same pole of the magnet in the contrary direction would rotate them, and they would then remain symmetrically in the opposite direction.

A precisely similar effect takes place in a soft iron rod, placed east and west a few inches above a direction needle. Upon drawing the south pole of a powerful natural magnet at a few centimetres distance above the wire from east to west, the north polarities of the molecules successively turn in the direction of west, following the attraction of the south pole, as previously seen on the small compass needles. The rod is now magnetised with its north pole west, as indicated by the direction needle below any portion of this rod. Upon passing the same south pole of the natural magnet in a contrary direction, the molecules all rotate, their north poles still turning successively to the south pole of the permanent magnet until its arrival at the end from which the first magnetisation commenced. The rod has now entirely changed its polarity, and its north pole is east.

This phenomenon is well known in the ordinary magnetisation of rods, where care is taken to draw the magnet always in a similar direction, or the poles would be reversed at each to and fro drawing. To account for this, on Coulomb-Poisson's theory, it would be requisite that—first, all the fluids be separated with their north fluids symmetrically in one direction, but on drawing back the magnet, these fluids would have to mix together, the north fluid passing through its south fluid to be finally opposite to its previous position, its coercive force doing the double work of allowing both fluids to mix and pass through each other, and finally keeping them entirely apart. Ampère's theory would require that from a haphazard arrangement the molecules should become symmetrically arranged upon the first passage of the magnet, then upon its reversed direction one half of the electric elementary currents should successively revolve in a contrary direction to arrive at neutrality before, finally, the other half followed the direction of the first half, and now all these currents would be revolving in the opposite direction to that upon the first magnetisation. We thus see that both these theories, whilst resting altogether upon assumption, are extremely complicated and improbable.

We might suppose, from the theory which I am advocating, that upon the rotation of the molecules there would be some disturbance or mechanical trepidation; and such is found to be the case, as first observed by Page, and afterwards verified by Dr. Joule and De la Rive, in the molecular sounds produced in iron upon its magnetisation. Reis's first telephone was founded upon these sounds, and Du Moncel has made numerous researches upon this subject.

In the last of my experiments cited, the sounds are too feeble to be heard, but by the application of the microphone these trepidations at once become audible.

That molecules of iron and other metals rotate with time, whose period becomes shortened by mechanical vibrations, is well known in metallurgy, the ultimate result being generally the passage from a fibrous condition, as in iron wires, to a high degree of crystallisation. For many years I employed a circular vibrating spring as the regulator of speed of my printing telegraph instrument, and although this spring was so regulated by means of a frictional break, or "Frein," as not to surpass its limits of elasticity, these springs were constantly breaking after a few days' use, and, as a matter of urgent necessity, I made special researches into the cause of this breaking after a few days constant vibratory action. I found at the point of rupture a high state of crystallisation. Fibrous iron would thus become thoroughly crystallised and break in one day; the number of vibrations for an instrument in constant use during 24 hours being 1,209,600. Thus we could roughly estimate the life of iron in the form of one of these springs at one million vibrations. Copper crystallised in one hour, and all metals and alloys were inferior to steel, except aluminium bronze. The latter springs would stand six weeks' constant use, or some fifty millions of vibrations. I finally resolved this problem by spreading the amount of vibrating work over a spiral spring containing three metres of steel rod wound into the same space as previously held by the straight rod of 30 centimetres; by this means the average life of these springs has become five years. Evidently the molecules of these fibrous springs must have rotated under the vibrations, in order to produce crystals. The same phenomenon is observed in axles of carriages receiving constant trepidations, large crystals being always found at the point of fracture. Again, if we rapidly magnetise and demagnetise an iron rod, we have the production of evident heat, due to the constant motion of its molecules.

Maxwell describes an experiment of Beetz, in which an exceedingly small filament of iron was deposited by electrotype, under the influence of a strong magnetic field, in order to arrive at the inherent polarity of comparatively few molecules, and, as its magnetic force was very great, he regards the experiment as conclusive. My own experiments show that we have far less external magnetic force from a solid bar than from a thin tube or flat bar of the same surface exposed to a limited exciting cause. We know that magnetism does not penetrate to a very great depth, and we also know that, if to a thin steel permanent magnet we place another piece unmagnetised, or, better still, a rod of soft iron, its external polarity is greatly reduced; consequently, the external evidence of polarity is not a direct measure of the degree of rotation, nor of the total inherent polarity of its mass. We may have a great superficial *external* rotation superposed upon rotations of an opposite nature, as will be seen later; and thus the internal molecules of a magnet often act more or less as an external armature in closing its circle of attractions.

I have stated my belief that the molecule itself possesses its inherent polarity, which, like gravity, is an endowed quality for which we have no more reason to suspect the cause to be elementary electric currents than that elementary currents should be the cause of gravity, chemical affinity, or cohesion and its polar power of crystallisation, most of which are affected by an electric current. We have a certain analogy between electric currents and magnetism, but not so great as the analogy between the magnetic polarity of a molecule and its other endowed qualities.

Magnetism, like chemical affinity, cohesion, and crystallisation, has its critical points. Faraday discovered that at red-yellow heat iron instantly lost its apparent polar magnetic power, to be as instantly restored at red heat, the critical point varying in iron, steel, &c., and being the lowest in nickel. This would be difficult to explain upon Ampère's theory, as we should have to admit the instant destruction or cessation of the elementary currents, to be again restored at a few degrees less temperature. It would be equally difficult to explain under my view, if it did not belong to a whole class of phenomena due to the possession by the molecules of various endowed qualities, of which chemistry and all our means of research can only teach us their critical points, without attempting to explain why, for instance, iron has a greater affinity for oxygen than gold. We know that it is so; we know that the molecules of all matter are endowed with certain qualities having certain critical points, and I can see no reason for separating their magnetic inherent polarity from their numerous other qualities.

wires and connections for a single station, consisting of battery, switch bell, Blake transmitter, and telephone, which is the arrangement in most general use. Care must be taken to follow the instructions for setting the battery in action and joining it up, also the remarks concerning stripping and cleaning the joining-up wires and soldering connections or joints. Having mastered the detail of connecting up a single station, the next step is fitting up a simple private line, as shown in Fig. 6. It has not in Fig. 6 been deemed necessary to give all the details of connections for joining

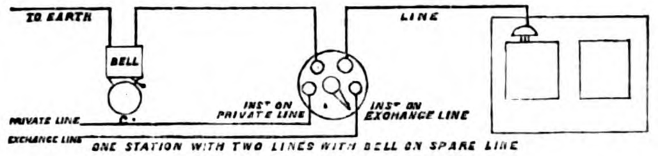

FIG. 12.

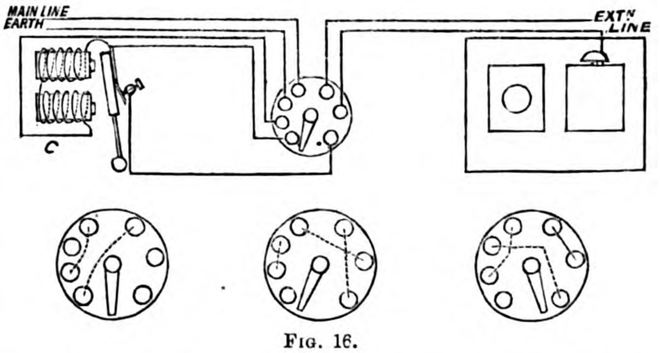

FIG. 16.

up a single station, as they are supposed to be known from the arrangement given in Fig. 5. The use of the various switches will be found explained further on. A list only of the requirements the various arrangements are contrived to meet will now be given.

Digitized by Google

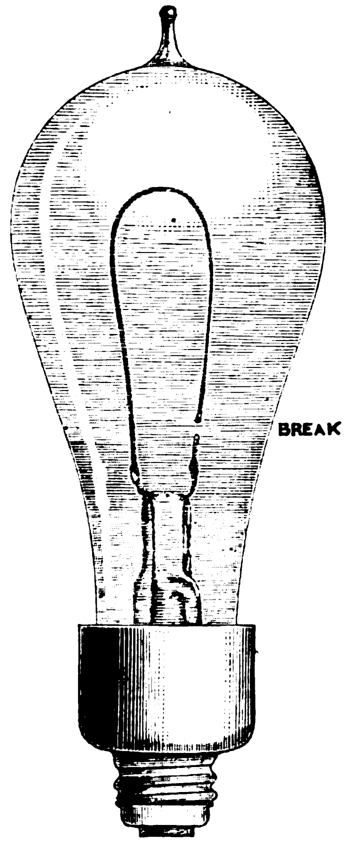
EXCHANGE ON PRIVATE LINE WITH TWO STATIONS AT ONE END IN DIFFERENT OFFICES OR ROOMS.—The switch should be placed near the instrument in most frequent use, as shown in Fig. 7. When with one instrument there is an additional bell placed where required to call attention to the instrument the switch should be near the instrument, as shown in Fig. 8. An improved arrangement of this kind is shown by Fig. 9. When the exchange line is extended, or requires a switch to be arranged to prevent the extension being used as a local private line, the handle must be kept to the right, as shown in Fig. 10. When it is required to use a private line as part of an exchange line, connected so that the private line station nearest the exchange can only speak on the private line, and not to the exchange, the bell should be connected so that the exchange can send a signal to be connected to private line when required, and the handle must be kept to the left, as shown in Fig. 11. When we have exchange and private lines running to one instrument, with an extra bell on the line that at the time is disconnected from the instrument, but so that the private line shall not be able to be connected through to exchange lines, the arrangement is as shown in Fig. 12. With two wires running into the exchange, and requiring to be put through at night, the arrangement is as shown in Fig. 13. When two lines have to be arranged in order to allow the intermediate station to speak up or down, or to be put through (the intermediate being then cut out, leaving only a bell in circuit), the arrangement is as shown in Figs. 14 and 15. Fig. 16 shows the same, but the switch converts the trembling bell C into a single stroke when in central position.

The extra sketches of the switches in certain of the above figures, with dotted lines between the terminals, show the circuits through when the handle is in the respective positions shown.

ON A PHENOMENON OF MOLECULAR RADIATION IN INCANDESCENT LAMPS.

BY J. A. FLEMING, B.A., D.SC.

Not long ago a curious phenomenon came under my notice in connection with the burning of Edison incandescent lamps, which presents sufficient interest to warrant me drawing the attention of physicists to it.



Edison Lamp used by Dr. Fleming.

As is well known, the carbon filament in the Edison lamp is of a horseshoe form. The two extremities of the loop are clamped into small copper clamps on the ends of the platinum wires, which are sealed through the glass. The ends of the carbon loop are electrotyped over with copper at the place where they are connected to the clamp, in order to make a good contact. If this precaution is omitted a loose contact may be formed, the result of which will be a generation of heat at that point. In the ordinary working the life history of a carbon filament is something as follows:—At some point or other the filament is probably thinner than at other places. At this place there will be a greater generation of heat and a higher temperature. Volatilisation of the carbon ensues, and the vapour condenses on the sides of the glass bulb, as far as I have observed, uniformly. If, however, the point of greatest resistance occurs on the copper clamp, then it is found that copper volatilises and deposits on the inside of the glass.

But what is most curious is that in this case an examination of the glass envelope shows that there is a narrow line along which no copper has been deposited. This is seen best by holding the lamp up before the light and slowly turning it round. In one particular position, easily found, it is best seen. Now, on examining carefully the position of the line of no deposit as compared with the carbon filament, it will be seen that it lies in the plane of the loop, and on the opposite side to that nearest to which the break of the loop has occurred. It is, in fact, *a shadow of the loop*, as shown in the illustration herewith.

The conclusion which must be arrived at, then, is that the copper molecules are shot off in straight lines, otherwise it is impossible that there should be this line of no deposit.

The most noticeable thing is that it occurs only when the deposition of copper takes place. I have never noticed it in an ordinary carbon deposit.

Hence there must be some essential difference between the vaporisation of the carbon and that of the copper. The carbon deposit resembles more the condensation of a vapour, and is uniformly distributed, but the copper deposit exhibits the character of a molecular radiation or shower taking place from a certain point.

The whole phenomenon calls at once to mind the beautiful researches of Mr. Crookes with vacuum tubes. Here, however, we are dealing not with an induction coil discharge, but with a comparatively low potential. I have never failed to see the effect in any lamp which has had a deposition of copper on its interior.

It is interesting to note how nearly the colour of transparent copper resembles that of transparent gold. The similarity of the surface colour of pure unoxidised copper and of gold is accompanied by a near resemblance in colour of the two metals in their films.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

(CONTINUED FROM PAGE 41.)

Many of the authors, who describe the sympathetic needle (dial) telegraph, speak also of another form, which seems to have been especially believed in by the Rosicrusians and Magnetisers of the last two centuries. It was supposed that a sympathetic alphabet could be marked on the flesh, by means of which people could correspond with each other, and communicate all their ideas with the rapidity of volition, no matter how far asunder. From the arms, or hands, of two persons intending to employ this method of correspondence a piece of flesh was cut, and mutually transplanted while still warm and bleeding. The piece grew to the new arm, but still retained so close a sympathy with its native limb, that the latter was always sensible of any injury done to it. Upon these transplanted pieces of flesh were tattoed the letters of the alphabet, and whenever a communication was to be made it was only necessary to prick with a magnetic needle the letters upon the arm composing the message; for whatever letter the one pricked the same was instantly pained on the arm of the other.†

List of authors of the sixteenth, seventeenth and eighteenth centuries, who either describe the sympathetic needle and sympathetic flesh telegraphs, or make a passing allusion to one or both of them; chiefly compiled from Mr. Latimer Clark's list of books shown at the Paris Electrical Exhibition of 1881, and from

* The author reserves all rights of translation.

† Upon this delusion is founded Edmund About's curious novel, "Le Nez d'un Notaire," in which he relates the odd results of sympathy between the notary's nose and the arm of the man from whom the flesh was taken. But it is not in novels only, that we read of instances of the marvellous power of sympathy in these enlightened days; witness the story of "The Sympathetic Snail Telegraph" of Messrs. Biat and Benoit, which went the rounds of the newspapers forty years ago, and which the curious—we were going to say sympathetic—reader will find fully described in "Chambers's Edinburgh Journal" for February 15, 1851.

the catalogues of the British Museum. As far as possible, only first editions quoted in full:—

1558 PORTA (GIAN B.). Magiae Naturalis, &c. Libri IIII. 8vo. (See page 90. Other editions: Antwerp 1561, 8vo.; Lugduni 1561, 16mo.; Venetia 1560, 8vo.; and 1665,12mo.). Neapoli, 1558.

1570 PARACELSUS (*i.e.*, Bombast Von Hohenheim). De Secretis naturae mysteriis, &c. 8vo. (Speaks only of sympathetic flesh, &c., telegraph. Numerous editions in British Museum.) Basileae, 1570.

1589 PORTA (GIAN B.). Magiae Naturalis, &c. Libri XX. Folio. (See preface to Book VII. for first clear mention of sympathetic needle telegraph. Other editions: Francofurti 1607, 8vo.; Napoli 1611, 4to.; Hanoviae 1619, 8vo.; Lugduni 1644 and 1651. 12mo.; London 1658, 4to.; and Amstelodami 1664, 12mo.) Neapoli, 1589.

1599 PANCIROLLUS (G.). Rerum Memorabilium, &c., 8vo. (See Book II. [Nova Reperta], chap. xi., Notes. This author refers to Scaliger [*Exotericarum exercitationem*, &c., exercit. 131], and Bodin. [*Methodus ad facilem Historiarum*, &c., chap. vii.], but they only speak of magnetic sympathy at great distances, without any reference to telegraphy. Other editions: two 8vo. Ambergae 1607 and 1612; four Francofurti 1622, 1629-31, 1646, and 1660; Lyon 1617; and London 1715.) Ambergae, 1599.

1600 DE SUNDE (J. H.) (*i.e.*, Daniel Schwenter). Steganologia and Steganographia, 8vo. (See page 127. Janus Hercules de Sunde is an assumed name. Hiller in the preface to his Mysterum Artis Steganographicæ 1682, says that it is a synonym for Daniel Schwenter Noribergense. And at page 287 he says, "Schwenteri is Est Hercules de Sunde." Other edition: Nürnberg 1650. 12mo.) Nürnberg, 1600.

1609 DE BOODT (ANSELMUS B.). Gemmarum et Lapidum Historia, &c. 4to. (See Book II. Other editions: Lugduni 1636, 8vo.; Lyon 1644, 8vo; and again Lugduni 1647, 8vo.) Hanoviae, 1609.

1610 ARGOLUS (ANDREAS). Epistola ad Davidem Fabricium Frisium. (He made what he calls a "Stenographic Compass," and held many agreeable conversations by its means with one of his friends). In Ephemeridae Patavii, 1610.

1610 ARLENSIS (PETRUS), of Scudalupis. Sympathia Septem Metallorum, &c. 8vo. (See chapter 2. This writer, a noted astrologer and alchemist, was the friend and fellow-citizen of Porta, to whom he seems to attribute the first conception of the sympathetic needle telegraph. His "Sympathia" was first published at Rome, but immediately suppressed in order that its grand secrets might not become known. It next appeared at Madrid in folio. The Paris ed. of 1610 was reissued at Hamburg in 1717.) Parisiis, 1610.

1617 STRADA (FAMIANUS). Prolusiones Academicae, &c., 8vo. (See Lib. II., Prol. VI. Other editions: Lugduni, 1617, and 1627. Sm 8vo.; Audomari, 1619, 12mo; Mediolani, 1626, 16mo.; Oxoniae, 1631, 8vo.; and again Oxoniae, 1745, 8vo.) Romae, 1617.

1624 VAN ETTEN (H.), (*i.e.*, Leurechon Jean). La Récréation Mathématique, &c., 8vo. (See page 94. This author is the first to give a drawing of the dial. H. Van Etten was a *nom-de-plume*. See *Notes and Queries* 1st series, Vol. XI., p. 516. Other editions: Paris, 1626; Lyon, 1627; and three London, 1633, 1653, and 1674. To the two latter is added a work of Oughtred, the editor, whose name is so conspicuous on the title page, that rapid cataloguers make him the author. Ozanam founded his "Recreations" on Van Etten; Montucla made a new book of Ozanam by large additions; and Hutton did the same by Montucla, so that Hutton's well-known work is at the end of a chain, of which Van Etten's is at the beginning. *Notes and Queries* 1st series, Vol. XI., p. 504.) Pont-à-Mousson, 1624.

1629 CABEUS (NICOLAS). Philosophia Magnetica, &c., folio. (See page 302.) Coloniae, 1629.

1630 HAKEWILL (GEORGE). An Apologie or Declaration of the Power and Providence of God, &c. Fol. (See page 285. This is second edition; a first appeared in [?] 1627, and a third in 1635. London and Oxford, 1630.

1631 KIRCHER (ATHANASIUS). Ars Magnesia, &c. 4to. (See pages 35 and 36.) Herbipoli, 1631.

1632 GALILEO (G.). Dialogus de Systemate Mundi, &c. 4to. (See page 88. Editions innumerable in British Museum catalogue. Fiorenza, 1632.

1636 SCHWENTER (DANIEL). Deliciae Physico-Mathematicae. (See page 346. This work is based on Van Etten's, *supra*. Two other 4to. editions appeared at Nürnberg 1651-3 and 1677). Nürnberg, 1636.

1638 MYDORGE (CLAUDE). Examen du livre des Récréations Mathématiques, &c. 12mo. (See Problem 74, pp. 140-44. This is a critically revised edition of Van Etten.) Paris, 1638.

1638 FLUDD (ROBERT). Philosophia Moysaica, &c. Folio. (See Sec. II., Lib. II., Memb. II., Cap. V., and Sec. II., Lib. III., *passim*. An edition in English appeared in London, 1659.) Goudae, 1638.

1641 KIRCHER (ATHANASIUS). Magnes, sive de Arte Magnetica. Sm. 4to. (See page 382. Other editions: Coloniae, 1643, 4to.; and Romae, 1654. Folio.) Romae, 1641.

1641 WILKINS (JOHN). Mercury, or the secret and swift messenger, showing how a man with privacy and speed may communicate his thoughts to a friend at any distance. 12mo. (See page 147. Another edition in 1694.) London, 1641.

1643 SERVIUS (PETRUS). Dissertatio de Unguento Armario, Sive De Naturae Artisque Miraculis. 12mo. (See para. 65, page 68. This work is printed in Rattray's "Theatrum," &c., *infra*.) Romae, 1643.

1646 BROWNE (SIR THOMAS). Pseudodoxia Epidemica, or Enquiries into very many received tenents, and commonly presumed truths. 4to. (See page 76. Numerous editions in the British Museum.) London, 1646.

1657 TURNER (ROBT.). Ars Notoria. The Notary Art of Solomon, showing the cabalistical key of magical operations, &c. 18mo. (See page 136.) London, 1657.

1657-9 SCHOTT (GASPAR). Magia Universalis Naturae et Artis, &c. 4 vols. 4to. (See Vol. IV., page 49. Copied from De Sunde and Kircher. Other edition: Bambergae, 1677. 4to.) Herbipoli, 1657-9.

1661 HENRION (DENIS) and MYDORGE (CLAUDE). Les Récréations Mathématiques, avec l'examen de ses problemes, &c. Premierement reveu par D. Henrion, depuis par M. Mydorge. Cinquieme et derniere ed. 12mo. (See Problem 74, pp. 158-61. This is only a revised edition of Mydorge's *Van Etten*, of 1638.) Paris, 1661.

THE ORIENTAL TELEPHONE COMPANY (LIMITED).

The third ordinary annual general meeting of this Company was held on Wednesday last, the 30th ult., at the City Terminus Hotel, Cannon-street, under the presidency of Colonel Gouraud.

The SECRETARY (Mr. W. G. Hall) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, I am sure you will all be sorry to hear, as I am to inform you, that our chairman is unable to be here to-day. He is prevented from coming through death in his family—not his immediate family, I am happy to say, but under circumstances which make it impossible for him to be here, as this very hour is the hour of the funeral. Under the Articles of the Association of the Company, in the absence of the chairman it falls to the directors to select one of their number to take the chair, and my colleagues have asked me to do so. I was not aware that I should be asked until a few minutes ago, so it is rather short notice. However, with slight indulgence on your part, I hope to discharge the duty to your satisfaction. As one of the Board I have been actively concerned in the operations of the Company, and am tolerably informed as to its position, and I shall endeavour to anticipate such inquiries as occur to me that you are likely to desire to make, and to give you such information as I have in a general way. If I should, however, not cover every point, any questions that you may wish to ask I shall be very happy to answer as best I can.

The meeting agreed to take as read the minutes of the general meeting held on 8th February, 1883, and they were accordingly confirmed and signed by the chairman.

The CHAIRMAN (continuing): Gentlemen: Before moving the adoption of the report, which I presume you will also take as read, as it has been circulated among all the shareholders, I will call to your notice one or two points which first occur to me. While this is stated to be the third ordinary general meeting of the Company, I think it might, with great appropriateness, be said to be a statement of really the first year's business of the Company. Its operations, as you know, extend over a very wide sphere, include many countries, widely separated from each other, and all of them at a great distance from home. The early operations of the Company were very much embarrassed by many things, but I shall only mention two or three out of the number. We took over from the vendors a "going" business in certain places, and with it agents whom they had sent out. Almost without exception I am sorry to say those agents had to be replaced, and a very large amount of the work they did had also to be replaced, not representing a great deal of money, but a considerable loss of time. However, we have one after another been able to substitute those people whom we thought inefficient by others whom experience has since shown to be worthy of the choice we made. At the last meeting the chairman was able to say to you that the business of the Company in several places was fairly under way. He reported to you—and I remember the statement received your approval, as it was felt that it would—that there were then 409 exchange subscribers. Considering that we had hardly begun at all, that was a very fair number. Since then we have been able to increase our subscribers to the date of the report, which you are aware is the 31st December, to 1,098, showing an increase of 160 per cent. I may mention that since that date the increase has gone on steadily almost everywhere, so that to-day, taking the latest advices we have, which are contained in a letter received this morning, the number is considerably above 1,100—nearer 1,200. Well, I think you will take that as showing a very satisfactory increase in the number of subscribers; and in this connection I may say that the increase would have been very much greater, no doubt, if obstacles of a certain character, which are experienced almost universally in this kind of business, had not been met with, namely, the difficulties first of all in what we call way-leaves, or the running of our wires. Of course, we may have subscribers, but we cannot connect subscribers with the exchange if people who own houses between the residences or offices of the subscribers will not allow us to attach our wires to their roofs. That is the case in some instances. In other cases we depend on poles, and the views of municipal and governmental authorities in various parts of the world very greatly differ as to that matter. At one place, for example, in India, we were not allowed to run our wires on roofs, but were compelled to erect poles. They were very fastidious not only about the construction but the appearance of the poles. We had to construct them to a certain design, which was of an ornamental nature, involving a considerable outlay in India, but it has this advantage in the long run, that we are able to connect subscribers with much greater rapidity, and wires suspended on poles are, as a rule, more permanent. In other places we have not been able to run poles where we should have liked, and had to content ourselves with the fixing of wires to the housetops. As this business goes on, this difficulty may be taken to diminish, and we may hope for a proportionately more rapid increase in the facilities for connecting subscribers, and consequently a more rapid increase in the number of subscribers. In the next part of the report reference is made to the placing of £7,000 to the reserve fund to meet possible claims under guarantees arising out of the formation of the Bombay Telephone Company, Limited, to which company, you are aware, we sold our rights in Bombay, and under our agreement with that company we have guaranteed a certain rate of interest upon a certain amount of the shares, and out of the cash proceeds of the sale of the Company's business and rights there we have as a matter of precaution placed this £7,000 to reserve. The next paragraph contains a reference to the interim dividend and the source from which it was paid. I think I may here say a word about the subject of the interim dividend, and in the remarks I am going to make I wish to answer questions put in letters by several shareholders, all of which have been answered, apparently, satisfactorily. Some little objection has been made by one shareholder about the amount of this interim dividend—not that he objected to receiving the money when he received it, but that it was so small that it did not seem worth while to trouble the shareholders with it. The smallness of that dividend arises chiefly out of this fact, that the denomination of the shares is small—£1—and the amount paid upon the shares is small (10s.), consequently if a shareholder had very few shares his dividend is very small, and one very effectual remedy for the inconvenience would, of course, be to hold a larger number of shares. Still, if we had consulted our own convenience entirely, as it involved considerable labour upon the Board, I do not think we should have declared that dividend; but we have done so, and it is better to receive complaints from shareholders at receiving a small interim dividend than at not receiving any dividend at all. The next paragraph in the report refers to the Board. There are no alterations in the Board, it is stated, but that is hardly the case. There are no new directors to be appointed at the meeting, but there are some additions to the Board, as you will observe, since the last meeting, when it was pointed out by one of the shareholders, with some regret, that there appeared to be absent from the list of directors two or three well-known names, and questions were asked as to the reason of that. The inquiry referred to the names of Mr. Edison, Mr. Bell, and Mr. Hubbard. The Board then told the meeting that those gentlemen would be requested to re-join, and they were accordingly communicated with and gave their assent to re-join with the exception of Mr. Bell. Mr. Bell unfortunately found, according to a recent statement made to us by Mr. Hubbard, his father-in-law, that in his domestic generosity he had divided his shares among his family, and did not hold the qualification, but he will re-qualify himself out of deference to the wishes of the Board and re-join us again. The auditors of the Company retire under the Articles of Association, and offer themselves for re-election. With regard to Egypt, in the early days of the Company—or, rather, in the earlier days, because they are still early—at the first or the last meeting I remember the chairman indicated the policy of the Board as being one which should lead it to the formation of separate companies in the different countries we are interested in, not with a view to financing or getting rid of something that we did not want, but with a view to strengthening our position in the various places, strengthening it through interesting residents in those places in the shares as well as in the subscription list and the exchanges, and with a view by this means of overcoming the ordinary obstacles in the way of an extension of this kind of business. Besides the Bombay Company, particulars of which are given in full in the accounts, and which were further explained at the last meeting, which authorised the agreement to be carried out between this and that company, a company has since been formed for Egypt. In Egypt the progress of the Company has been very satisfactory indeed, and it continues to be so. Almost every mail brings us news of additions to the list of subscribers, and besides the business, not only at Cairo, but also at Alexandria (the only place where we are established which was entirely wiped out by the late war), it has been re-established, and the growth has been more than rapid in proportion to the time than it was on the first establishment prior to the late war. It will be a matter of satisfaction to you all to know that the service has been so satisfactory in Egypt, and has been so appreciated by the public and the Government, that they have recently extended our concession, which was limited to Cairo and Alexandria. It now includes Port Said, Ismailia, Zagazig, Suez, Mansourah, and Tantah, in all of which profitable business, it is believed, will be done; and we hope, before very long, to connect most if not all of those places, the one with the other, which will give a great stimulus to the whole business. An independent company has been formed to carry out the same policy as was employed before, and which was announced to you with a view to placing the shares in Egypt. No shares, however, have yet been placed there. Some time ago, when the Company was formed, in connection with which I should, perhaps, mention that a majority of the members of this Board are interested, it was thought desirable to have an independent chairman, and the directors were fortunate enough to secure for the position General Fraser, C.B., R.E., who for a long time was at the head of the Public Works Department in the Government of India, a gentleman of very excellent position, and no doubt a very good chairman he will make. Being deputy-chairman of that company, I may say that he has given a great deal of time and attention to it, and has a great belief in its future. At the time of the formation of the Company we began negotiations, or rather met overtures, to that end from some residents in Egypt, for the purchase of an interest in the shares of that Company. We are practically, perhaps, committed more than I wish we were to the promise of a sale of those shares, though we have not yet sold them. I think I am rightly expressing the feeling of the Board when I say that we shall not feel any particular regret if the negotiation falls through, as every day we see that the value of those shares is increasing. To-day the net receipts of the exchange itself show quite a respectable dividend on the shares which this Company holds in that company—the Telephone Company of Egypt. However, if the negotiations terminate in the sale of those shares we shall feel satisfied, as it is after all only carrying out the policy of the Company in interesting the people in various localities. In India—in Bombay, the agreement is completed with regard to the sale of this Company's interest there. We have received the money due to us, and we have received the shares of the business, which is now in the hands of a local company. The local Board, I am happy to say, consists of just the class of gentlemen you would all like to see there, and they are taking a great interest in it, and I have no doubt they are doing all they can. But I am bound to say that there the development is not quite equal to, at least, my expectations. It may go on more rapidly later on. They have not yet succeeded in tapping the native community. When they have done that, there and in the other countries in which we are concerned, we may look for a very large increase over present business. To do that they must, no doubt, vary their system of tariffs—possibly reduce them, and with that variation, even if it involves reduction, I feel certain that if once they get the natives to use their communication, there will scarcely be a limit to its extension. In one place, Egypt, the native element has already commenced to come in, and that is regarded as a very important circumstance. At Calcutta a local company has been formed, and there is a gradual increase in the business. There, as at Bombay, we have not yet secured any native subscribers. In time we shall, no doubt, do so. In Burmah the business is steadily increasing, though recent troubles in the rice trade have very materially retarded its progress. In Madras the progress is improving under improved construction. There was a case where the construction had to be practically replaced. We had to re-run practically all the wires. That is attributed to the climatic effects on the sort of wire used. We have obviated that, and endeavoured to meet the climate on its own ground. At Colombo the number of subscribers is small, but it shows a tendency to grow with lower rates. At that place the rates were too high, and that has been the case with many others. The communication is worth less to the subscriber when there are fifty than when there are 300 subscribers, and I am glad to say that in America, according to a statement I received this morning, they are adopting a policy of

Digitized by Google

starting at low rates, say, with fifty subscribers, and in that case they charge fifty dollars a year. They charge five dollars extra a year with each additional fifty they get, and I think we should consider the same plan. In the Straits Settlements, the Singapore Exchange is a steady dividend yielding concern, which is steadily growing. I am told that Mr. Pell, our manager for Singapore, has just entered the room, and if I state anything that is incorrect I shall be glad if he will tell us. The business there is steadily increasing, and I congratulate Mr. Pell on the prompt way in which he has remitted us money. We wish that in every other place we had the same experience. We look to Singapore for a very material increase next year.

Mr. PELL: It is increasing daily.

The CHAIRMAN: That means a great deal. An increase of one a day would give us more than 300 a year. The local community are very much satisfied with the management, and we do everything we can to maintain its efficiency. We have independent assurance of that from members of the community there. In China the business has been disappointing. We have had many difficulties there. We were met, in the first place, by an existing establishment competing with us without any right to do so, but it is sometimes found that people will assume rights they have no claim to. We found that the case in China in more than one place, and we decided, as has been our practice everywhere, to assert our own rights, amicably at first, and then, if not successful, in some other way. In China, as the result of the course we took, we succeeded in bringing the people there to recognise our rights. In the result we have made a compromise with them, which, without troubling you with details, is entirely satisfactory. We have no competition or difficulty of that kind there now, but I am sorry to say that we have met there another difficulty which is entirely original, and differs from anything that we have experienced anywhere else. It appears that the Chinese were a great deal mystified by the extraordinary performances of the telephone at the beginning. In some cases they noticed, in certain conditions of the wind and the attachments to the roofs, that there was a certain musical sound, which I have heard sometimes myself, and which might be compared to the Æolian harp. But they thought it an evil spirit, and they have described it in their euphonious language, Fung Shui. That has retarded our development there, but I believe now that they are changing their minds about the influence of this mysterious spirit, and subscribers are increasing, we hope to overcome even Fung Shui. In the Hawaiian Islands we hope to receive a dividend during the current year. The business there, as you see from the figures in the report, is steadily increasing. That is one of the most remarkable cases of telephonic development I know anything about, and the accounts, when referred to, will offer me the opportunity to say something more specifically. In Mauritius we delayed beginning until recently, when representations were made to the Board from Port Louis, and we determined to open an exchange there on the assurance that it would meet with reasonable support at the outset—support that will cover our expenses, and show some prospect of a good return. The material and an electrician have already been despatched thither. The most significant remark I can make of a general character, after all, would be to tell you that the net receipts at the present time from what I may call really established business—the receipts from the payments by exchange subscribers themselves, without looking to anything from the sale of rights to companies, or the cash we may receive from such sales, give promise of a reasonable dividend in themselves upon our share capital, which is small as compared with the business we are doing and the extent of our operations. That, I think, you will all regard as satisfactory, and perhaps the most satisfactory feature of the business. In the accounts it might, perhaps, be better for me to abstain from any remarks, and answer any questions that may be asked. There are, however, one or two things which occur to me to remark upon. In the London expenses there are several items that struck me when I saw them come out in the books, although I was cognisant of the details that made them up throughout the year. Among them I would mention advertising, stationery, and printing. It seems to me that they were very large, and I am satisfied that they are larger than they will be next time. The printing item I looked into thoroughly, and I found it was due to getting a kind of information which we felt we must get so as to know every week what the position of the Company was. We have devised forms which we sent to all our agents, and when we were getting them printed, as the chief expense was the setting up, we thought we would get a larger number at once. With regard to the advertising we shall cut this down, as we do not find that it advances our business very much. As to the principal item, the directors' remuneration, I should call your attention to the fact that, while under the Articles of Association the directors are entitled to receive as their remuneration £2,500 a year, they have voluntarily amongst themselves decided for this year to take only £1,500. It is a pretty large Board, and, as my experience goes, an experience which I am happy to say is chiefly confined to telephone Boards, I think it very moderate remuneration considering the work done. We meet weekly—sometimes two or three times a week—and I have no doubt that our taking £1,500 instead of £2,500 will meet with your approval. I would say in this connection, speaking, perhaps, of myself, that I would not have you understand that our taking £1,500 this year should be regarded as meaning that we will not take any more in the future. My own impression is that when our dividends are materially increased you would be only too glad to pay us the remuneration prescribed by the Articles of Association, but till we pay a higher dividend I feel that we could not take more than we have done this year. Our interest in the Hawaiian Bell Telephone Company is in shares of the local company, and we have there an agent who looks after our affairs. We anticipated some little difficulty in that quarter, and we appointed this agent, a gentleman of very excellent position there, and together with a member of the legal profession who happens to be an old comrade of mine, they are looking after our interests. It was well for us that we had some one representing us, as we met an awkward suggestion there some time ago when a question was raised as to the legality of our holding shares in that company. In the accounts the nominal value of those shares is taken at something over £1,000, but the net receipts are so large that they show a very much higher value than the nominal value of those shares. In fact, although we have taken them in the accounts at their par value, we have been offered this year five times their amount, and as we thought they were worth more, we declined that offer. But we made a counter offer which was not accepted. However, immediately after that we were met with this pleasant intimation, that we were not entitled to any shares at all. We resisted this preposterous demand, and only the other day we got a telegram from our agent saying that we had won the case in court there. As to the expenses in London during construction, I would call your attention to the fact that the balance brought down as profit is reached only after charging to the year the whole of the London expenses. We thought that a proportion only of this item might be fairly charged this year, but after consultation with the auditors we thought that it would be better to be on the safe side and charge the whole in the working expenses of the year. I do not know that I need call attention to the fact, but we only paid a dividend upon £75,000 less than the total amount of the shares issued, the total amount being 297,000 shares. 75,000 of those shares we issued will not receive any dividend till the ordinary shareholders of the Company (practically preference shareholders) have received for five consecutive years dividends of 6 per cent. Mr. Griffiths, the auditor, calls my attention to the fact that the shares received in part payment of the Bombay sale have not been dealt with in the profit and loss account. Whatever may be realised ultimately for these shares, and no doubt it will be a substantial amount, will be entire profit. On the credit side of the balance-sheet there is a charge in reduction of preliminary expenses—an amount of £2,704. This is taken as a profit realised practically to the Company from the sale of the 20,000 ordinary shares which were authorised some little time ago, which were issued at a premium, and that premium represents this £2,700. At the time of this issue the shares were at a considerable premium above that, and it was an advantage to the shareholders to receive them at that price. They were all taken up by the shareholders, and the premium was dealt with in this way. All these stocks and stores mentioned in the balance-sheet are taken at their intrinsic value, and perhaps most of them have gone into actual construction since. Well, gentlemen, nothing further occurs to me voluntarily in the way of remark. I would have been more thorough and more satisfactory in my observations to you had I had a little notice that I was to take the chair. Before moving the adoption of the report, however, I should be happy to hear any questions that may be asked by any shareholders. Mr. Hall calls my attention to a matter that had escaped my mind, and which I should not omit to mention before sitting down, namely, that we are honoured to-day here, for the first time, at the Board with the presence of the most distinguished member of his profession in the world, Sir William Thomson. Before I resume my seat I should like to make this general remark, on the subject of the telephone industry. I presume I am not exaggerating when I say that there is no parallel in the whole history of applied science to the rapidity of the growth of the telephone industry as an industry throughout the world. I think its growth has been more rapid in the West than in the East, and relatively all the way round the world, unless you call the Hawaiian Islands in the East. I do not know exactly where they are. But certainly in America the development has been almost beyond conception. I received yesterday two or three figures, which I am sure it will be interesting to you to hear. The exchange subscribers in the United States number (this is not to date; no doubt the number is larger now) 100,000. The increase last year was 27,000. The mileage of the wires run last year was 30,000 miles—telephone wires—and the value of the telephone property in the United States, having no regard to foreign telephone companies at all, is estimated, at the market value of the shares, at 100,000,000 dollars, or £20,000,000 sterling. In England the development has been less rapid than in America, but there have been infinitely greater obstacles to contend against here of the character I have referred to, and also the difficulty that there was with the Government. In our own countries, I mean the countries where this Company is interested, I think, from the comparative slowness of the Eastern mind to open itself to such advantages, our progress has been very satisfactory indeed. We have one advantage that I have not yet mentioned as compared with England, an advantage which they have in America as compared with England, we have not to pay, with one exception—an English province—anything for the privilege of doing our business. That is the case in America, and the case in most of the places in which we offer it. We pay tribute to the Government for this privilege only in India, and they unfortunately take their example from the home Government, where we have, as you are aware, to pay. In Egypt and everywhere else we are regarded as public blessings, and we are not taxed for Government purposes. I shall be happy to answer any questions which any shareholder may have to put to me.

Mr. WRIGHT: I should like to ask how many shares there are in the new Bombay Company and our right there, and also how many in the Calcutta Company and our right there, and also for how many shares we have in each case given a guarantee under our agreement?

The CHAIRMAN: You would like to know the number of shares on which we guarantee.

Mr. WRIGHT: The number in that company.

Mr. A. F. PETTIFER: What is the amount you claim from the Indemnity Commission with respect to the losses of the Company at Alexandria? Then, again, I see in the balance-sheet £25,742 entered under the head of debtors. Will you be good enough to tell us if that is in your opinion a good asset?

The CHAIRMAN: In answer to the first question, the capital of the Bombay Company is 960,000 rupees, of which 840,000 are issued, and of the latter 480,000 claim our guarantee. Now, if the Bombay Company has the same development, that good luck that most other telephone companies have, we shall not be called on for anything under that guarantee. It would not surprise me, however, if during the first year we were called on for some portion of it, but my opinion is that with anything like reasonably good management on the part of the local Board there we shall on the average in the five years have nothing whatever to pay, and I hope that will prove to be the result. With regard to the other inquiries, I should prefer the honourable shareholder excusing me from answering his first question, for obvious reasons—the question what is the amount we have claimed for our injuries at Alexandria. It might prejudice the interests of the shareholders to do so, and I think you will see that. We have made a claim which we believe an honest one, and which if received will—I should hardly like to be reported as saying entirely compensate us—but we have claimed what we thought we might reasonably claim of the Government, and if we get that we shall be satisfied. As to the debtors, they have all paid since. That answers that question in the most satisfactory manner. We have got the cash. It was almost entirely owed by the Bombay Company.

Digitized by Google

The SECRETARY: The capital of the Calcutta Company is 10 lacs of rupees, of which 880,000 rupees are issued. Our guarantee will extend to probably something like five lacs of rupees. We have not yet received the final accounts of that, as the transaction is not yet closed.

The Rev. F. C. FINCH: I should be very glad to know in what proportion the directors have attended the Board meetings. Another question I should like to know is the amount of shares they hold, and I should also be glad to know about the 20,000 shares which were hawked about in the auction mart.

A VOICE: 10,000 shares.

The CHAIRMAN: In answer to the last three questions I may say that the attendance book will show the number of attendances of the directors, and I think that question would be best answered to the satisfaction of the shareholder if I were to say that that book is at his service after the meeting. It is on the table. There are several gentlemen on the Board who, after having left the Company because they could not attend the meetings, living as they did out of the country, who are now on the Board again at the express wish of the shareholders. At this moment it may occur to you that there is a very small representation of the Board here. But Mr. Pender's absence I have accounted for, Sir Alexander Armstrong is here, Mr. Bigelow is ill, Mr. Cargill is abroad, Mr. Carnegy is here, Mr. Edison is in America, Mr. Hubbard lives in America, and Sir William Thomson is present. Mr. James Pender is in America, and Sir Julius Vogel is unavoidably absent to-day. He is only just returned from Australia, and, by the way, I may make some more reference to Australia which I omitted before. There the position of the Company is this, that we have not done all that we would care to do. There were some little matters in connection with which we succeeded in interesting Sir Julius Vogel when he was in Australia. Since his return he has laid before the Board a very full report, the substance of which is that we have rights there which can be enforced, if necessary, through the medium of the law, but we hope to avoid taking such measures. At the present moment there are agents in London who have full power of attorney to deal with us, and during the last two or three weeks some of us have spent two or three hours a day with those gentlemen over this question. As to the amount of the shares held by the Board, I do not suppose the shareholders would insist upon knowing the exact amount of the shares held by each director. I do not know whether it would not be out of his right to have the information if he wanted it. But I always prefer straining a point to give a shareholder something he has no right to if it will give him satisfaction. I may say, then, that the directors hold a very large amount of the share capital. I can say this further, and I speak with positive knowledge of the point, one is the largest shareholder in the Company. That, I think, will be all the information that the gentleman will require on that subject. The qualification is, perhaps, larger in this than in any other company.

Mr. FINCH: Will you tell us the qualification?

The CHAIRMAN: £1,000—1,000 shares. As to the hawking about of certain deferred shares, that was rather a sore point with myself. I do not know whose shares they were. You will fully understand that in a business of this character, the shares resulting from a transaction of this kind, numbering 75,000, would naturally be distributed among a great many people. There were several interests. The Bell and the Edison interests were separate in the beginning, and they together, in the first instance, received all these shares; but they had a great many partners, and they have been divided up. I can tell you that these shares were not my shares, or the shares of any of my immediate friends, so far as I am aware. We did consider whether we should take some notice of the circular, and were advised that we could not do so. The facts stated were, I believe, substantially correct, although it is, of course, a matter of surmise how soon the vendors' shares will receive a dividend. I did not form the impression, which the gentleman seems to have formed, that that circular was prejudicial to the interests of the Company.

Mr. FINCH: The shares went down very much.

The CHAIRMAN: I do not think in connection with that.

Mr. FINCH: It was at the same time, and they gave this circular as the reason for the fall on the Stock Exchange.

The CHAIRMAN: They give very strange reasons on the Stock Exchange.

Mr. FINCH: I had six or eight circulars.

The CHAIRMAN: I had as many. I should hope that the circular did no permanent injury to the Company. While on the subject of the shares, I should like to say this—and I say so on the authority of one who has had as large an experience as any one—whose experience dates, indeed, from the birth of the telephone. I speak of myself—that whatever may be the present price of shares in this Company, or whatever was the market price in the past—and you will remember that they have been at more than 100 per cent. premium at a time when a great many shares were not so well worth the price which these shares are selling at now—it is my deliberate opinion, and I think the facts which I have given you justify my opinion, that, regardless of the past or present market price of these shares—the market price being influenced by sometimes entirely extraneous causes—there has been no time when the shares of this Company were intrinsically worth anything like what they are worth to-day. That is my opinion. You may take it for what it is worth.

Mr. ST. JOHN ACKERS: As one of the largest shareholders, perhaps the meeting will pardon me if I ask a few questions and make a few remarks, not with any view of cavilling or finding fault with those gentlemen who have given their time to the interests of the Company, but rather, if I might say so, to strengthen the Company generally by having a few facts more thoroughly known. I believe that the more thoroughly our position is known the more thoroughly will the public appreciate it. A good many of the questions I had intended to ask have been asked and answered, most of them in a very satisfactory way. There are a few points as to the accounts that I should like to speak about. With regard to bills payable, and so on, I take it that the answer is similar to that which you gave to the gentleman who asked a question about the debtors. I take it that those were sums owing but not due when the accounts were made up to the 31st December.

The CHAIRMAN: That is so.

Mr. ST. JOHN ACKERS: That is satisfactory. As to the Alexandria indemnity I appreciate your answer, but I should like to ask whether our claim is one of those claims which have already been acknowledged? Certain claims, as I understand from the public papers, the indemnity commissioners already acknowledge.

The CHAIRMAN: A certain class of claims.

Mr. ST. JOHN ACKERS: I should like to know whether ours are included in that category. As to the question of our guarantee, I should like to ask whether there is any guarantee for other purposes over and above the guarantee under certain circumstances to pay a certain percentage on certain shares of the Bombay and Bengal companies. The guarantees here are put in a general form, and I should like to know whether there are any others.

A SHAREHOLDER: There are no guarantees as to Bengal.

The CHAIRMAN: You wish to know whether our claim for our losses at Alexandria is included in that class of claims which we understand will be allowed. I do not think we have information that will enable us to answer that question. We may say this, that they have taken our matter up and gone into the question, and probably by now have come to a conclusion on the merits of our claim. They have gone through the statement of our claim, and have had the amount of our losses examined into by experts. That is as far as I am able to answer the question, and I hope it will be satisfactory to you. There is this important addition that I may make—that our agent, who, by the way, is a most excellent and efficient man, and I do not know a more efficient man in the whole telephone world than our agent at Alexandria, advises us that he believes our claim will be met in full. He may be disappointed in that, and I do not give it as my opinion. As regards the Company's guarantee in connection with the Bombay and Bengal Company's shares, whether there is any further guarantee, if I understand your question, it is—does our guarantee involve us in the payment of anything beyond the deficiency in the net earnings of the Company upon a certain amount of shares?

Mr. ST. JOHN ACKERS: The question was if there was any other guarantee other than those in connection with those companies.

Mr. ROBINSON KENDAL: Your guarantee does not extend to Bengal, but only to the Bombay Company.

The CHAIRMAN: But Mr. Ackers's question is, having referred specifically to two guarantees, are there any others? At present in the accounts there is only one guarantee, but I have gone beyond that. I wanted to come down to the date of the report. Owing to the distance of our base we could not hold our meeting earlier. There are no other guarantees.

Mr. ACKERS: There is the question of these very great and very heavy expenses—the expenses in London. No one can look over these accounts and not notice that our expenses are at the present time out of all proportion to our business. I would earnestly ask the directors if there are not certain expenses which could not be materially reduced other than those mentioned. While you gave the expenses in London, you gave no idea of the expenses abroad. I take it—though I may be wrong—that there are other very considerable expenses abroad besides those which we have in the accounts for agents or managers, or whatever they be. It would, of course, be satisfactory to the shareholders to, at any rate, know that we are not paying large amounts to agents or managers in those countries where we are not either making satisfactory progress at present or where there is not immediate hope of satisfactory progress. As to the directors' remuneration—and here I touch on what is a most delicate point for a shareholder to speak on—we cannot, of course, expect gentlemen to undertake heavy work without adequate remuneration; but, at the same time, in your speech you alluded to the fact that you did not pledge yourselves to accept £1,500 for the current year's services of the directors. I would only say, in reply to that, that I earnestly hope, I will not say advise, the directors will be moderate with regard to what they accept till this Company has got on to a firmer basis—that is, more advanced than at the present time. I believe the basis is thoroughly sound and good, but we are in our infancy. Remarks are made outside. A gentleman spoke about an effect which had been produced on the Stock Exchange. I can only say that, directly this report got on the Stock Exchange, the first remarks I heard were as to the amount of the directors' remuneration in proportion to the profits. I, therefore, earnestly hope that this is a question that you will consider not only amicably, but in the forbearing spirit which has characterised the directors in the early days of the Company, which I hope may be continued perhaps even to a greater extent than has been already done. A good chairman deserves good remuneration, but I would put it to you whether there are not rather more English directors than are necessary for the business of the Company. I think it is quite certain that all the different interests ought to be represented on the Board, and, therefore, I think it is quite wise that Mr. Edison, Mr. Hubbard, and those gentlemen who had interests which we have absorbed, should be represented on the Board. But then I say the question I hope the directors will consider is whether there cannot be a saving as to other gentlemen who are on the Board. I do not propose to take up any further time with regard to many points I had desired information on, as I think that nearly all of them have been answered. I earnestly hope that we shall work together, both the shareholders and the directors, and that we may have a much more prosperous year this year. I hope in what I have said that I shall not be considered as antagonistic, but that it will be considered that I have only offered what I hope are legitimate remarks.

The CHAIRMAN: For my own part—and I only state what I believe every director would say—as to the last point of the hon. shareholder, there can be no objection to the matter or the manner—certainly not to the manner—in which he has presented his points. As regards the reduction of the London expenses, other than the directors' remuneration, I touched on one or two points which are having our careful attention. I do not believe there is very great room for reduction there, though everything counts in a case of this kind. Those expenses will have our attention, and I hope they will be dealt with in a manner which will meet with your approval. As regards the directors' remuneration, I am sure you will see that, when we have taken £1,000 less than we were entitled to, we have some ground for expecting a recognition of the fact from you, and that has been expressed by the last gentleman. Certainly the matter will have our very careful attention in the future. I said that our taking that £1,500 must not be considered as a precedent for our taking only £1,500 in future. I may say also that neither does it commit us to the taking of £1,500. I should say that if we do not improve even beyond the present very satisfactory position of the Company it will be open to us to consider whether we should not take less, and the reduction would not be much individually divided among the directors. I would say that I should be very much dissatisfied at taking less than I now get. I do not think I get enough, and I do not think my

Digitized by Google

colleagues get enough. If we pay you a material, a more substantial dividend, as I think we shall, I believe that the shareholders would not begrudge us substantial remuneration. I think that the proceedings of the Company have shown that there is no difference whatever between the shareholders and the directors. With regard to the expenses abroad, they do not appear in detail in accounts of this kind. We have been under certain expenses abroad under two classes of service—one of agencies for our general business prior to the establishment of these local companies. It would have been more or less confusing to bring the details of those expenses into account. Those expenses have all had our very careful consideration, and the principal one we are under at present is one that comes to an end almost immediately—within the next two or three months. It is in connection with the services of a gentleman who has been our immediate negotiator in these cases. He has not had an unreasonable salary, but a good one. We gave him a percentage in accordance with certain results, and the result to him has been a fair remuneration, while the result to us, on the whole, has been satisfactory. The other expenses in connection with the formation of these companies we have purposely excluded from the accounts, for a reason which, when I explain, you will all appreciate and approve. We were obliged necessarily to have agents who do this kind of business so far from home—agents on whom we could depend, and who must be of the highest position in their communities, and while we have had to pay them, we have in no case paid them excessively. To publish the terms of our payments to them would, however, be like publishing the details of another man's business. I think, however, I may ask you to accept from me the assurance that we have paid no unreasonable commissions anywhere, and wherever we have secured the services of local gentlemen as directors we have invariably secured the services of such gentlemen as you would like to see in those positions.

Mr. A. F. Dewing: I am really sorry that I cannot agree with you about the Company being in such a very flourishing position. I do not consider that you have paid more than 2½ per cent. The other 2½ per cent. divisible is covered by the premium on the shares you issued, that we paid 12s. 6d. for, but which are now worth about 7-16 in the market. I do not know the view my brother shareholders take, but I do not at all hold that we are in the good position which you have represented us as being in.

Mr. Kendal: There is one point I should like to refer to. I agree somewhat with this gentleman, that this is not the best possible statement that could be submitted to the meeting. When you examine the figures you see that no great amount has been earned. We must also take account of this—that we have been working for eighteen months and not twelve months. The state we have to consider is not as to what was done last December, but as to what has been done to-day. We must see clearly, I think, that the position of this Company is to be regarded as at the present moment and not as on the 31st of December. As to the expenses abroad from the formation of the Company, are they included in the £48,000, or are they deducted from the cash? It appears to me it is not so much a question of the expenditure in London. If the directors take care in this £48,000 to see that it is reduced to a *minimum* they will have fairly earned their remuneration. I should like to ask, as a matter of inquiry, if the amount of those charges is included in the £48,000 for the formation of exchanges, or if the amount of the commissions is deducted from the amount received in cash or shares from the subsidiary companies, the net amount being then entered.

The Chairman: The answer I should have given you, Mr. Griffiths, who has audited the accounts on behalf of the shareholders, has noted down. Before showing the profit on the sale of exchanges all the costs of every nature are deducted.

Mr. Kendal: Deducted from the amount received?

The Chairman: Yes. With regard to the remarks of the gentleman who preceded Mr. Kendal, I would say that he has misunderstood the accounts. We have not taken the premium on those shares into the accounts. The comparison he has made is hardly fair. When those shares were taken by the shareholders—and no one took more than I did—at that premium, it was a decided advantage, and you could have sold the shares at that time at a considerable premium beyond that which was paid.

Mr. Pettifer: Will the directors take any fees in the Egyptian, China, or Japan Companies?

The Chairman: I presume they will, but I cannot say they have not taken any. There has been nothing to take. The capital, you observe, has not been placed.

Mr. Pettifer: What I want to understand is, when the capital has been placed will the directors take separate fees?

The Chairman: So long as the directors and the shareholders are only ourselves in this Company, the directors will not take such fees. I should think not. It has not been our practice to do so. I should scarcely think it would be an honourable thing to do, and it is not likely to be done. I now move: "That the accounts made up to 31st December, 1882, together with the directors' report, now submitted to the meeting, be approved and adopted, and that a final dividend for the year ending 31st December, 1882, of 2½ per cent., free of income tax, on the ordinary shares of the Company, be and is hereby declared."

Sir William Thomson, LL.D., F.R.S., M.I.C.E.: I have much pleasure in seconding the motion, and in doing so I would take the opportunity of congratulating the Company on the progress which has already been made. The work undertaken is, as you all know, one of very wide-spread ramifications, with centres of action over a very large area of the globe, and the amount of work involved in making arrangements to spread the operations of the Company so far and wide is something very serious. I have not myself taken part in the work of the Board, being only an *ex officio* member; but I am sure that my colleagues of the Board have worked exceedingly hard, although the profits hitherto have not been as large as we could wish. The business, however, seems to be in the most healthy condition, and it offers every prospect of a large increase, and an increase that may in every respect be looked forward to as giving a highly satisfactory future to the Company.

The Chairman put the motion in the usual manner, and it was carried. Continuing, he said: Gentlemen, the shareholders have to appoint an auditor. Messrs. Deloitte, Dever, Griffiths, and Co. were auditors last year, and their appointment expires under the Articles of Association. They, however, offer themselves for re-election, and I shall be glad to move that they be reappointed, or some shareholder might move it.

W. H. Newton, Esq.: I shall be happy to propose that the same auditors be appointed for next year at the same remuneration.

J. Sala, Esq., seconded the motion.

The Chairman put it, and it was carried.

Mr. Kendal: There is one question suggested to me that I should ask you. Do the directors contemplate—I would not say the probability, but the possibility, of making a call?

The Chairman: I think I ought to be able to answer that question very promptly in the negative. They cannot contemplate it, as it has not been mentioned among themselves, nor do I see any immediate occasion to consider it. That terminates the meeting.

A Shareholder: I beg to move a vote of thanks to the chairman for his conduct in the chair.

Mr. Kendal: I beg leave to second it.

The Chairman: On behalf of our absent chairman and my colleagues, both present and absent, I thank you very much for the patient manner in which you have heard all I had to say.

The meeting then separated.

SUBMARINE CABLES TRUST.

The twelfth ordinary annual meeting of the certificate holders in the Submarine Cables Trust was held at the offices, No. 66, Old Broad-street, on Tuesday last, under the presidency of John Pender, Esq., M.P.

The Secretary (Mr. Lewis Wells) read the notice convening the meeting and the minutes of the last meeting, which were confirmed by the present meeting. The report of the trustees was taken as read.

The Chairman: There is very little left for me to say beyond what is contained in this report. Our investments are not only in a good but in an improving position, more particularly the Eastern and Eastern Extension Companies. Their dividends have been increased, and that, of course, places our certificates in a better position. Last year, however, the Anglo-American went through a period of considerable competition and reduced rates, and our return from that source—which is a large investment in our trust—was less, and, consequently, gave us less money to invest in the purchase of our certificates. We consider that our certificates are now at a fair price, although, compared with the real value of the stocks, they are probably something like £10 below their actual intrinsic value. However, this value is more or less fluctuating. When an opportunity occurs, as we have money, we go on purchasing our certificates. We have very little in hand just now for that purpose, and therefore are not in a position to say we are buyers at the present time. With these remarks I beg to move, "That the report and accounts now submitted to the certificate holders be received and adopted."

The Marquis of Tweeddale seconded the resolution, which was at once unanimously passed.

On the motion of Mr. Aston, seconded by Mr. Cashman, the auditors, Messrs. John G. Griffiths and John Gane were re-elected.

A Shareholder: Are we likely to be free from further competition in regard to the Anglo-American Company, or can you give us any further information on this subject?

The Chairman: I can only give my own individual impression. After a considerable storm there is generally a calm, and we have had a great deal of storm and excitement about competition in the Atlantic. At one time there was a similar combination of the Press with Mr. Garrett, of the Baltimore and Ohio, but I think it was more talk than anything else. It always struck me that Mr. Bennett was not likely to do it on his own account, or that Mr. Garrett was likely to do it on his own account, as there was no response from the general public or their friends. It has assumed no form or shape, and there is, moreover, nothing to warrant another set of cables. We have now eight cables in the Atlantic. Those eight cables are capable of doing, I suppose, probably, three times the amount of work they are doing, because science has enabled us to duplex them, so that every cable, if in perfect working order, counts for two cables, or does as much work as two. Therefore, our cables are in excess of requirements at the present time. What they may be ten years hence I do not know, but meantime we are keeping so far ahead that the service is maintained in such a state that no one can complain, and I think there are really now chances of a lull. We have got as an ally, not as an enemy, perhaps the most bold and enterprising man, and as his cables are associated with ours there is not likely to be any opposition from that quarter. The Western Union is a very formidable body, and people will think twice before they tackle such a company. Then the Eastern Company is doing fairly well. I always think myself that telegraphs ought to pay better than they do. The Eastern Extension is also doing fairly well, and is likely to do better; and, looking at our investments as they stand in the list, I think they are of a very satisfactory nature. The public, too, are beginning to believe now in telegraph property as a permanent investment. Before, it was regarded as very speculative, but now we have pretty well, from our experience, made it a real property, which people believe in, and as they believe in it, knowing as we do the difficulty of investing money for our reserves at 4 per cent., we shall find that there will be a good demand for our certificates—a good security, with something like 6 per cent. I would, therefore, rather back the improvement than the retrograde.

Mr. Keenliside then proposed a vote of thanks to the chairman and the trustees for their excellent management.

Mr. T. H. Wells seconded the motion, which was carried unanimously.

The Chairman, in reply, said: This is not a big concern excepting in this—that your Board have, besides looking after the details of the trust—that is not so onerous—to watch the other companies from which we derive our revenue. We are engaged in those undertakings more or less, and, therefore, whatever we say you may regard as safe, and near the truth. We are always glad to have our services recognised by you, and we are somewhat disappointed if you go away without saying we have at least done the best we can for you.

The proceedings then terminated.

River Plate Telephone and Electric Light Company.—The report of this company states that the net revenue for the year was £4,475. The Preference shares are entitled to a 9 per cent. dividend.

Digitized by Google

LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).

The fifth ordinary general meeting of this Company was held at the offices, Old Broad-street, on Thursday, under the presidency of John Pender, Esq., M.P.

The SECRETARY (Mr. William Payton) having read the notice convening the meeting,

The CHAIRMAN stated that for the last three years they had paid a regular dividend of 2½ per cent., and the dividend they recommended on the present occasion would make the distribution for the past year at the same rate. They had had to draw to a slight extent on the amount carried forward on the last occasion in order to maintain this rate of dividend, which it was their desire to do. Since they had come to that decision they had received payment of a portion of the debt due to the Company by the Uruguayan Gouernment. There still remained £7,000 to be adjusted in connection with that debt. By keeping steadily at the Government they hoped to be repaid. He then referred to the sources from which the Company derived its revenue, and stated that the falling off in the cable receipts had been owing to the inequitable competition of the Brazilian Government land lines. He was hopeful that that Government would yield to the pressure which was being exerted with them in connection with this matter. He next alluded to their intention to endeavour to introduce certain economies, and stated that the Board had set the example in that direction by giving up £200 of their fees to the reserve fund. He concluded by moving the adoption of the report, and the payment of the dividend recommended.

Mr. HOLLOCOMBE seconded the motion, and in reply to questions,

The CHAIRMAN stated that they would be quite prepared to recommend the sale of the Company's property on fair terms. He spoke hopefully of the prospects of the undertaking. The motion was carried unanimously, and the retiring directors and auditors were re-elected.

A vote of thanks to the chairman and directors brought the meeting to a close.

CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY (LIMITED).

The second ordinary meeting of this Company was held on Thursday, at the Cannon-street Hotel, under the presidency of Sir Julius Vogel, K.C.M.G.

The CHAIRMAN regretted that his task on the present occasion was much less agreeable than on the last occasion. No one had been more surprised than he at the unfortunate turn the affairs of the Company took in the past year. When he left this country for Manitoba last May he thought that their affairs were in as favourable a condition as they could desire, but on his return he found that a variety of adverse circumstances had happened. Acting under advice, they made a compromise for a large claim which had been made for the manufacture of telephones. Then the Post Office last June unexpectedly gave notice of the termination of the contract with the Company for 15,000 telephones. Again, one of the objects of the Company was to manufacture telephones for the United Company and its affiliated companies, but during the past year they had scarcely done anything for them. They had also had to employ a good deal of their means in respect to telephonic business in Austria. The contract of the Post Office had since in some measure been returned to them, and friendly and cordial relations had again been established with the United Company, for whom they would now manufacture telephones on the terms of the original contract. Important concessions had been obtained with regard to Austria, where there was every promise of a large business. A little difficulty which had arisen with the concessionaires would, it was hoped, be satisfactorily arranged. Their interest in the telephone in the River Plate was considerable, and it promised to be a good field for the enterprise. The directors still hoped to make the Company a success.

Mr. P. CARNEGY, C.I.E., seconded the motion, which was carried after some discussion.

FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED).

A meeting of the shareholders in this Company, convened by Mr. Harcourt Turner, was held at the City Terminus Hotel, on the 29th ult.

Mr. TURNER, having been voted to the chair, read a letter which he had received the previous night from the secretary of the Company, who, writing by instructions of the directors, amicably cautioned him to do nothing which should aid the enemies of M. Philippart or prejudice this Company and the French Company. A memoir was, the letter added, in hand for translation, showing that M. Philippart had been the victim of treacherous attempts. Continuing, the chairman said he thought he had better tell them what had passed between him and the secretary, and leave them to discuss what they considered best to be done under the circumstances. The first thing that attracted his attention was the payment of a dividend last January, because those of the shareholders who attended the meeting in November, when Sir Arthur Otway was in the chair, would remember that they were told that the Company was then doing no business. The old directors went out of office very soon after. The very first thing which the new directors did was to make a call of £1 a share, and also to declare a dividend of 3s. a share. On looking into the Articles of Association he found that the directors had very ample powers to determine themselves what was capital and what was income, and he therefore thought it was of no good to take any further steps in the matter. Affairs then went on until the arrest of M. Philippart. He then again wrote to the secretary, and reminded that gentleman that he had told him (the chairman) that the general meeting was to be held either in March or early in April, and that if not held by April he should take such steps as he should think fit to bring the affairs of the Company fully before the shareholders. To that letter he had received an answer, saying that the Board had fixed the 10th or the 17th of this month for holding the general meeting. Those dates had gone by, and it was quite clear to his mind that unless the directors had the "screw" put on them they would do nothing for the shareholders. At the beginning of this year M. Philippart was on the register of shareholders as the owner of over 20,000 shares, but on the register for April 11 the number of shares held by him had been reduced to 50; but at the same time there appeared the Société la Force et la Lumière for 30,000 odd shares. It seemed to him very strange, after the praise they heard from M. Philippart respecting the undertaking of the Company, that he should reduce the number of shares held by him to 50, which he must hold in order to retain his seat on the Board of the Company. In the letter he had referred to the secretary stated that the accounts of the Company were about to be audited, and that they would be duly submitted to each shareholder before the general meeting. It had occurred to him (the chairman) that if they could have the accounts that day it would be advantageous, and he had endeavoured to get them, knowing that the effort would be useless after he had issued his circular. He had had a reply from the secretary to his communication of the 14th. He read the letter, which stated that it had been thought advisable by the directors that the accounts should be made up to the 30th of April, and that the audit had not yet been completed. Owing to M. Philippart's detention, which the directors had reason to hope was only temporary, it had also been thought best to delay the general meeting, as the directors were assured that the interests of the shareholders would be better served if M. Philippart's attendance could be secured. Continuing, the chairman observed that the shareholders were aware that, by the Articles of Association, the accounts had to be made up to the 31st of December, and presented to the shareholders. Not a word was said in the circular of the secretary about extending the time, though he (the chairman) would be glad to see them made up to the 30th of April. It, however, seemed rather a strange way of doing business. That being the state of affairs, the question was, what could they hope to do in the way of business? As he had pointed out in his circular, the chairman of the Company was under arrest, and from all he (the chairman) could hear, he was likely to be in durance vile for some time. He had asked the shareholders to meet together to consider what was the best course to be adopted, and he should be happy to hear any suggestions to that end.

After some little discussion, Mr. L. A. Solomon moved, and Mr. W. D'Oyly seconded, a resolution to the effect that a committee of investigation should be appointed from among the shareholders to inquire into the present position of the Company, and to report theron to the shareholders with a view to decide as to what action should be taken thereon, but that no active steps be taken by the committee until after June 26, the day appointed by the directors for their annual meeting.

The resolution was passed, and subsequently Messrs. Ponsonby, Harcourt Turner, L. A. Solomon, and Mr. D'Oyly were appointed members of the committee, and it was decided that Sir Charles Clifford should be also asked to join it.

A vote of thanks to the chairman for convening the meeting, brought the proceedings to a close.

ELECTRIC LIGHTING OF LEEDS.

Supplemental particulars relating to the proposed lighting by electricity o portions of the municipal buildings at Leeds for the Corporation.

The attention of companies and persons who may intend submitting tenders for lighting by electricity the places mentioned in the particulars issued by the Electric Lighting Committee of the Corporation of Leeds, and dated the 21st inst. (*see The Electrician* for May 26, p. 43), is directed to the following supplemental particulars having reference to the proposed lighting. At a meeting of the committee, held at the Town Hall, Leeds, this day, it was reported that in response to the invitation of the committee for suggestions as to probable improvements generally in the proposed scheme of lighting, several communications had been received from companies and persons desirous of tendering, suggesting for the consideration of the committee the desirability of the clause in the particulars issued on the 21st inst., relating to the employment of a particular type of dynamo-machine being modified, when after the subject had been considered it was resolved—"That, having regard to the suggestions now made, the committee conclude to modify the clause so as to allow companies and persons tendering to suggest for use such types of dynamo machines as they may consider best adapted for employment in connection with the particular system of lighting comprised in the tender."

It was also resolved that the following further alteration be made in the particulars, viz.:—That the clause on page 10 reading: "All wires must be carried to the various groups of lamps by means of wood mouldings, to harmonise with the walls and mouldings of the ceilings, &c., so as to cover up and preserve the wires," be cancelled, and that in lieu thereof the following clause be substituted, viz.:—"The committee, will, at their own cost, open in the walls and other places such receptacles as may be necessary to receive interior wires, and that after the contractor has placed the wires in position, the committee will cover up and make good such receptacles, and will also cover with wood mouldings such wires as may be exposed, or which may require protection."

Also, that the clause on page 10, reading:—"Incandescent lamps.—'Swan' or other approved lamps of not less than 20 candle-power must be used. The committee will, however, reserve to themselves the right to accept or require to have employed any other description of incandescent lamp of the same candle-power in connection with the proposed installation" be cancelled, and that in lieu thereof the following clause be substituted, viz.:—

Incandescent lamps.—"'Swan' or other approved lamps of not less than 20 candle-power must be used."

By order of the Electric Lighting Committee.

(Signed) GEORGE W. MORRISON,
Town Hall, Leeds, 29th May, 1883. Town Clerk.

TURKISH PATENTS.

NOTICE TO PATENT AGENTS AND INVENTORS.

The undersigned having established a special agency in Constantinople, are prepared to SECURE PATENTS in TURKEY for all inventions not yet in use in that country for £35, including drawings of average amount.

Special terms to Patent Agents.

W. P. THOMPSON and CO.,
BRITISH and INTERNATIONAL PATENT AGENTS,
6, LORD-STREET, LIVERPOOL
(and 323, HIGH HOLBORN, LONDON).

WRIGHT and MACKIE PATENTS for GLASS-BLOWING by MACHINERY.

The HAMMOND ELECTRIC LIGHT and POWER SUPPLY COMPANY (Limited) are open to CONTRACT with companies and individuals holding patents for Incandescent Lamps for the MANUFACTURE either of the GLASS WORK or the COMPLETE LAMPS.

They are also in a position to SUPPLY almost any description of PHILOSOPHICAL or CHEMICAL GLASS WORK in large quantities at greatly reduced prices.

The HAMMOND ELECTRIC LIGHT and POWER SUPPLY COMPANY (Limited),
110, CANNON-STREET, E.C.
PHILIP A. LATHAM.

FAURE-SELLON-VOLCKMAR ACCUMULATORS.

On and after 1st January, 1883,
THE
ELECTRICAL POWER STORAGE COMPANY
(Limited),
4, Great Winchester-street Buildings, E.C.,
will be prepared to supply
FAURE-SELLON-VOLCKMAR ACCUMULATORS.

Which can be used in conjunction with any Incandescent Lamp or Electrical system, and afford the only reliable and economical means of Lighting Private Houses, Hotels, Theatres, Ships, Railway Carriages, &c., by Electricity.

Particulars and prices post free on application.

CARBONS.—For all kinds of ELECTRIC LIGHT, Leclanché, Bunsen, and Grenet Batteries, Telephones, &c.

The best, cheapest, and most reliable for every kind of Lamp.

Carbons of any size, shape, and of every description manufactured to order at the shortest notice.

JAMES W. COLUMBINE,
2, Carlisle-street, Soho-square, W.

INSULATED ELECTRICAL WIRE, Silk, Cotton, or India-rubber covered. Conductivity guaranteed. German Silver Wires for Resistance. Braided Handle Cord, Silk Cord for Electric Bells, &c.—WILLIAM RICKARD, Derby London Agent (stock kept), EDWIN HOLLOWAY, 2, Gutter-lane, E.C.

THE
ELPHINSTONE and VINCENT
CONTINUOUS CURRENT DYNAMO-ELECTRIC
MACHINE.
SHUNT MACHINES to drive 400 Swan Lamps now ready.
For prices and other particulars apply to
Mr. THEODORE BAXTER, 79½, Gracechurch-street, E.C.

THE NEW MATERIAL

or ENGINEERS (Sanitary and Hydraulic), ELECTRICIANS, AXLE MAKERS, BRASSFOUNDERS, PUMP MAKERS, RAILWAY COMPANIES, CARRIAGE and WAGGON BUILDERS, &c.

SUBSTITUTE FOR LEATHER, RUBBER, AND PERCHA.

It is unequalled for Washers of all kinds, Hot and Cold Water Packings and Plumbers' uses generally, Insulators, &c.

THE PATENT VULCANISED FIBRE

Is supplied in Sheets from 1-32in. to 1in. in thickness, and in two qualities: Flexible, 2s. per lb.; Hard, 2s. 3d. per lb.

MOSSES & MITCHELL, 68, 69, 70 & 71, CHISWELL ST., LONDON, E.C.

NOTES.

SOUTH AMERICA.—The cable between St. Elena and Payta is repaired.

ARABIA.—Telegraphic communication is restored with Jeddah and other places in Hedjaz, Arabia.

NEW CABLE.—The French Cabinet have been discussing the question of laying down a cable to connect Saigon and Tonquin.

TELEGRAPH CONSTRUCTION AND MAINTENANCE COMPANY.—This Company's Bill received the Royal Assent by commission on the 31st ult.

ELECTRIC RAILWAY BRAKE.—*L'Electricité* learns that M. Achard's electric brake has been definitely adopted by the directors of the State railways.

LONDON ELECTRIC WIRE COMPANY.—This company has removed from Wenlock-buildings, Ironmonger-row, to Anchor Works, Playhouse-yard, Golden-lane, E.C.

THE BRITISH ASSOCIATION.—Professor Lord Rayleigh has been nominated by the Council of the British Association as president for the meeting at Montreal in 1884.

LEEDS GAS.—It may be interesting to electricians to know that the official report on Leeds gas for the past month gives its average illuminating power as 17·18 candles.

M. PHILIPPART.—A telegram from Brussels, dated June 6, states that M. Philippart was provisionally set free on that date, on giving bail to the amount of 15,000fr.

TENDERS WANTED FOR ELECTRIC LIGHTING.—Tenders are being invited for lighting the Royal Aquarium, Westminster, and St. James's Hall, Burnley, by means of electric lights.

TELEGRAPHIC EXTENSION IN CANADA.—The telegraph line between Qu'appelle and Touchwood Hills has been successfully completed, and the through line to Humboldt is expected to be at work shortly.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended May 31 are £3,028, as compared with £3,261 in the corresponding period of 1882.

THE TELEPHONE IN CANADA.—According to recent news from the Dominion, arrangements are being made for telephonic communication between Kingston and Toronto, Hamilton and Western Points.

ELECTRIC LIGHTING IN BAVARIA.—The King of Bavaria's new palace at Neuschwanenstein is lighted internally by means of Edison lamps, whilst Jablochkoff lights are employed for external purposes.

THE BRUSH SYSTEM IN BRAZIL.—The Brazil Government have confirmed the patent held by the Brush Electric Light Company. The latter are establishing forty of their lamps in the streets of Campos.

DIVIDEND.—The directors of the Brazilian Submarine Telegraph Company have declared an interim dividend of 3s. per share, or 6 per cent. per annum, for the quarter ended 31st March last, and payable on the 25th inst.

ELECTRIC LIGHT ON A CHINESE IRONCLAD.—The Chinese ironclad, "Ting-Ynen," which has recently been built in a German dockyard at Stettin, is lighted by means of 240 Edison lamps. Ting-Ynen means, we believe, eternal peace.

THE TELEPHONE IN COLLIERIES.—The Société John Cockerill, of Seraing, near Liege, Belgium, have recently introduced the telephone into one of their collieries. The instruments are said to work well at a depth of 350 metres (about 383 yards).

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for May, 1883, were £22,600. For the period 1st January to 31st May, 1883, they amounted to £99,520, whilst for the corresponding months of 1882 they were £94,150, and for the same period of 1881, £93,172.

ELECTRIC LIGHTS FOR CARRIAGES.—The Vienna correspondent of the *Daily News* telegraphed from that city on Sunday night as follows:—"Last night Baron Rothschild's carriage was lighted by electricity. The accumulators were placed under the coachman's seat. The electric lights were inside the usual lamps."

MORE WIRES.—To meet the expected increase of traffic on the introduction of sixpenny rates the General Post Office are putting up two new wires between London and Glasgow, one between Bristol and Glasgow, and one between Newcastle-on-Tyne and Glasgow. Others are to be put up in course of time as funds allow.

A NEW STEAMER.—The "Gabo," a new steamer, built by Messrs. J. Key and Sons, at Abden, Kinghorn, Scotland, for Messrs. W. Howard, Smith, and Sons, of Melbourne and Sydney, was launched this week. She is 280 feet long, and has a gross tonnage of 2,042 tons. It is stated that she will be lighted on the incandescent system.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of May was 3,848, estimated to produce £3,300, against 3,408 messages, producing £3,544 in the corresponding month of last year. The traffic receipts for the month of February, estimated at £3,900, realised £4,036.

APPOINTMENTS.—Lieutenant-Colonel Alexander Lipoianu has been appointed Director-General of Posts and Telegraphs in Roumania.—We understand that Mr. O. Loring, for some time one of the electricians of the Anglo-American Brush Light Corporation, has been appointed manager and chief electrician to the Northern Electric Light, Power, and Appliances Company (Limited).

WEST COAST OF AMERICA TELEGRAPH COMPANY.—This company give notice that telegraphic communication with Valparaiso, Mollendo, Arica, Iquique, Antofagasta, Santiago de Chili, Buenos Ayres, and all telegraph stations in Peru, Chili, and the Argentine Republic is now re-established *viâ* Galveston. The tariff per word from Great Britain to Valparaiso is 14s. 8d., and to Buenos Ayres 13s.

ELECTRIC LIGHTING IN AN ASYLUM.—We understand that the Committee of the Gloucester County Asylum have decided to light a portion of their new buildings with electric light, and have entrusted the contract to Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, London. Otto gas engines, with Dowson's patent gas, Sellon-Volckmar batteries, and Woodhouse and Rawson incandescent lamps are to be used.

A HAND-DRIVEN DYNAMO.—Mr. W. E. Fein describes in *Carl's Repertorium* a hand-driven dynamo on the Gramme system, which is capable of producing in a voltameter from 180 to 200 cubic centimetres of gas, and of maintaining at a glowing heat a platinum wire half a millimeter in diameter, and half a metre long. At 1,200 turns per minute the E.M.F. is equal to from eight to ten Bunsen elements.—*Wiedemann's Beiblätter*, 1883, No. 1, p 55.

TELEGRAPH STORES WANTED.—The North-Eastern Railway Company are inviting tenders for the supply of telegraph

Digitized by Google

apparatus and telegraph wire and line stores for the six months ending 31st December next. Forms of tender may be obtained on application to Mr. Graves, Telegraph Department, York, and tenders must be sent in to the Secretary of the Company, at York, sealed and marked "Tender for Telegraph Stores," not later than noon on the 22nd instant.

Messrs. Johnson and Phillips.—We are informed that Mr. Bennett Pell, late of the Eastern Extension Telegraph Company, has become associated with the firm of Messrs. Johnson and Phillips, telegraph engineers and electricians. We think that this well-known firm are fortunate in securing the co-operation of a gentleman of such activity and wide telegraph experience, and Mr. Pell will, we are sure, find ample scope for his energies in his new sphere of labour.

Notes from Ceylon.—The *Colonies and India* says :—"Very severe lightning storms have occurred in Colombo, the surveyor-general's office being struck and the occupants much alarmed. It was believed that this was due mainly to defective insulation of the newly-erected telephone wires. The subscription to the telephonic exchange in Colombo is to be reduced from the former almost prohibitory rate of 300rs. to half that sum, and arrangements have been made with the Government Telegraph Department for concurrent working."

Electric Exhibition at Vienna.—Four hundred exhibitors have given notice to the Committee of the International Electrical Exhibition to be held here, says the Vienna correspondent of *The Times*—216 from Austria, 70 from Germany, and 19 each from England and Italy. There are already 36 notices from France. Ten Austrian insurance companies jointly undertake the insurance of the objects exposed. The French, Belgian, and German railway companies have consented to a reduction of the tariffs for visitors to the exhibition.

Steamship "Cotopaxi."—It will be remembered that a fire occurred on board this vessel a short time since, doing considerable damage, and, amongst other things, destroying the electric light wires with which she was fitted. The dynamos (Bürgin) were saved at the time of the fire, and have been replaced. The ship has also been re-wired throughout by Messrs. R. E. Crompton and Co. She belongs to the Orient line of steamers, and was lighted by Swan incandescent lamps for the first time some fifteen months ago, Messrs. Crompton and Co. carrying out the work.

The Postal and Telegraph Services.—The annual conference in connection with the United Kingdom Postal and Telegraph Service Benevolent Society was held at Bristol on Monday last, when upwards of fifty delegates attended from forty districts in various parts of the kingdom. The report showed that no less than twenty-six districts had been added in they ear,and 835 new members enrolled. The widows and relatives of deceased members had received £6,000 in the past year, bringing the total payment to £20,880 since the establishment of the society. Next year's meeting will be held at Edinburgh.

Steamship Lighting.—The ss. "Clan MacArthur," which has been built for Messrs. Cayzer, Irvine, and Co's Clan Line, by Messrs. Scott and Co., of Greenock, started from the Clyde on Saturday, the 2nd instant, for a preliminary cruise with a large party on board. The vessel has been lit throughout with incandescent lamps by the Glasgow branch of the Edison Electric Light Company. We understand that the owners have been so pleased with the complete success of the lighting that they have placed the lighting of another steamer, the "Clan MacIntosh," with the Edison Company, without inviting tenders from other firms.

The Telephone in Brazil.—By an imperial decree of the 21st April the Government confirmed the patents granted by the United States to Alexander Graham Bell for his telephone. A company has been formed in Rio de Janeiro, under the title of the Companhia Nacional de Electricidade, with Mr. C. P. Mackie as president, and has purchased the sole right to use the Bell and other patents in Brazil from the Tropical American Telephone Company. The Companhia Nacional have granted a license for Rio de Janeiro and Nitheroy to the Companhia de Telegraphos Urbanos, of which Mr. W. J. Donshea is superintendent and Mr. Victor Dias manager.

Electric Lighting at Cardiff.—The Brush lamps that have for some time past been used to light St. Mary-street, Cardiff, have been replaced by Crompton arc lamps, the current for which is supplied by a Bürgin dynamo. The front of the theatre and the Washington Hotel are also lighted by Crompton lamps. The work has been carried out by Mr. Lascelles Carr, of the *Western Mail*, who introduced the electric light into his own offices some time ago. We believe that a considerable amount of electric lighting work is on the point of being commenced in this locality by Mr. Carr, in conjunction with the Swan United Electric Light Company.

Huddersfield Technical Schools Exhibition.—We understand that the order for the lighting up of this exhibition has been secured by Messrs. Kingsland and Smith, of Leeds, agents and district managers for the Yorkshire Brush Company, and Messrs. Ferranti, Thompson, and Ince (Limited). This exhibition, which will be similar to the one held at Bradford last year, is to be opened the first week in July, and is expected to remain open till about November A 40-light Brush machine will be used for lighting up the the weaving and other sheds by Brush arc lights, while a 300 light Ferranti dynamo will be used for operating incandescent lights in the rest of the building.

Electric Lighting in the West End.—Lord Randolph Churchill's house, No. 2, Connaught-place, W., has been lighted by Swan lamps. A 3 horse-power Otto gas engine has been fixed in the cellar under the porch, and drives a compound Bürgin machine, which charges 60 one horse Faure-Sellon-Volckmar accumulators in the daytime. The current is taken from the accumulators at night as required. Should it be necessary, the engine and dynamo can be driven at night, and the current passed through the accumulators, which then act as regulators. About 80 Swan lamps are used at present. The work has been satisfactorily carried out by Messrs. R. E. Crompton and Co., of Mansion House-buildings.

Electric Lighting in Switzerland.—The project of lighting the canton of Vaud, in Switzerland, by means of electricity is engaging the attention of several engineers in Lausanne at the present time, says *L'Electricité*. A central station intended to supply the motive power will be established at Vallorbes, near the source of the Orbe, and by this means the waters of lakes Joux and Brevets will be utilised. Water will be brought from near the Bonport Mills to Vallorbes by means of a tunnel 800 metres long. The quantity of water that will thus be placed at the disposal of the engineers will be about 2,500 litres per minute (about 100 gallons), and will be capable of giving to the turbines of the station a motive power equal to 500 horses (the French h.-p. is smaller than the English), sufficient to light 2,500 electric lamps.

Tampering with Telegraph Boys.—At the Stockton Police Court, a few days ago, Thomas Higgins, bricklayer,

Digitized by Google

was brought up on a charge of soliciting and endeavouring to procure certain telegraphic messages from W. H. Laing and J. E. Lumley. Mr. C. J. Archer appeared on behalf of the postal authorities, and showed that the prisoner met the lads in the streets, and endeavoured to effect an arrangement with them as to what had won the big race—meaning the Derby—and if they would tell him he would give them half-a-crown; the object being to obtain the winner of the race, and then bet on it before the result was generally known. The boys, on returning to the office, told Mr. Brown, the postmaster, and hence the prosecution. Other evidence confirmatory of the above having been given, prisoner was committed for trial, bail being accepted.

Time Signalling.—In the annual report of Mr. W. H. M. Christie, astronomer royal, he says:—"There has been no case of failure in the automatic drop of the Greenwich timeball. On three days the ball was not raised on account of the violence of the wind. The Deal ball has been dropped automatically at 1 p.m. on every day throughout the year, with the exception of five days on which there was a failure in the telegraphic connection, of one day when the ball was accidentally dropped 4sec. too soon by telegraph signals, and of 14 days when the current was weak and the trigger was released by the attendant. On 12 days the ball was not raised because of the violence of the wind. The Westminster clock has maintained its high character, its errors having been under 1sec. on 66 per cent. of the days of observation, between 1sec. and 2sec. on 25 per cent., between 2sec. and 3sec. on 6 per cent., and between 3sec. and 4sec. on 3 per cent. The error has never exceeded 4sec."

Electric Lighting on a Yacht.—The "Empress," steam yacht, which we mentioned some time ago as about to be lighted by incandescent lamps, is now lying in the Thames, off Greenhithe. She has been fitted up with 32 Swan incandescent lamps, which are fed by Faure-Sellon-Volckmar accumulators supplied by the Electrical Power Storage Company. The accumulators are charged by means of a shunt wound Bürgin dynamo, driven by a three cylinder Brotherhood engine fitted up near the yacht's engine room. Steam is supplied to this engine by a separate boiler made by Messrs. Cochrane, so that steam can be got up when lying in harbour, or when the yacht is sailing and fires damped down under her other boilers. The fittings have been supplied by Messrs. Faraday and Co., of Berners-street, Oxford-street, W., and are adapted for candles as well as electric lamps. The installation has been carried out by Messrs. R. E. Crompton and Co. The yacht was built by Earle's Shipbuilding Company, of Hull, for her owner, Sir A. Walker.

Magnetic Observations at Greenwich.—In his annual report, which has just been issued, Mr. W. H. M. Christie, astronomer royal at Greenwich Observatory, makes the following remarks with reference to the year's magnetic observations:—"A great improvement," he says, "has been made in the photographic registrations by the substitution in June of Morgan and Kidd's argentine-gelatino-bromide paper, with ferrous oxalate development, for the old process. The large temparature correction of the vertical force magnetic has been reduced to less than one-fourth of its former amount by some alterations which were carried out by Mr. Simms last autumn. There has been considerable magnetic activity during the year, the month of November (which was characterised by the appearance of a very large sun-spot) being particularly disturbed with remarkable magnetic storms on November 17, 19, and 20, and many interesting cases of lesser disturbance. The magnetic disturbances on October 2 and November 17 were accompanied by brilliant auroras."

Electric Lighting in Malta.—On Tuesday, May 29th, the Chevalier E. Rosenbusch, C.E., on behalf of the Eastern Electric Light and Power Company, gave an exhibition of incandescent lighting at his residence in Strada Mercanti, Valletta. "A large number of visitors were present, amongst whom we noticed," says the *Malta Standard*, "His Excellency the Governor, Captain Borton, General and Lady and the Misses Feilding, Colonel and Lady Crichton, Honourable Captain Carr, Sir Adrian and Lady Dingli, Baron and Baroness Testaferrata Abela, and others. As soon as His Excellency arrived, the La Valette band, which was in attendance, struck up "God Save the Queen," and the street was brilliantly illuminated with the electric light. The exhibit went off with great success. The lights displayed consisted of side lights, chandeliers and table lamps of variegated colours, and gave every satisfaction to those present, who heartily congratulated Chevalier Rosenbusch and Mr. William Robinson, the electrical engineer, who lucidly explained the system to the company."

Electric Lighting for Dundee.—At a recent meeting of the Dundee Gas Commission it was announced that the following terms had been arranged with the Brush Company with reference to their provisional order:—That the company should appropriate £20,000 of capital for providing a station in Dundee forthwith, and deposit £3,000 in security for the performance of the obligation. That the Police Commissioners should be allowed to open streets at the expense of the Brush Company for the purposes of new works, and that electric lighting could be demanded by the Police Commissioners on such terms as might be settled by an arbiter, failing agreement with the company; further, that one or more streets might be lighted with one or more lamps in any street without any general obligation being undertaken. The area of supply was also fixed in terms of the Gas Commissioners' original requirements, and the clauses adjusted providing that if nothing was done within four years the order should lapse, subject to the Board of Trade imposing such terms upon the Brush Company for their breach of order as might be deemed right.

Electric Light on Ships.—The Pacific Steam Navigation Company's ss. "Liguria" has just been fitted with fifty Swan lamps by Messrs. R. E. Crompton and Co. The current is supplied by a Bürgin dynamo machine, driven by an eight horse-power vertical engine supplied by Messrs. Marshall and Co., of Gainsborough. This engine gives more power than is at present required, but has been supplied with the idea of providing power for double the number of lamps at present in use. The latter are coupled up two in series, and are fitted in the ordinary candle lockers, so as to throw light into two cabins and the passage at the same time. There are sixteen lamps in the saloon, two to each table, instead of the five candles hitherto used; they have medium opal globes and plated fittings. The machine and engine are fitted up in the ship's engine room, and are looked after by the engineer on watch. One lamp lights the smoking room on deck. The work was carried out to the satisfaction of Mr. Shoolbred, consulting electrical engineer to the Pacific Steam Navigation Company, by Messrs. R. E. Crompton and Co., of Mansion House Buildings, Mr. Lockhart having charge of the installation.

Secondary Batteries.—Messrs. R. Tatham and A. Hollings, of Rochdale and Salford, respectively, have taken out a patent for a new method of constructing plates for secondary batteries. Their process is as follows:—"Paper pulp

Digitized by Google

prepared from unsized paper, cotton, linen rags, or other vegetable fibre is mixed when moist with twelve times its volume of peroxide of lead for the positive element or anode, and with a similar quantity by volume of sub-oxide of lead for the negative element or cathode, so that the mixture or compound contains about 93 per cent. by volume of the metallic or active agent. The proportions by volume of the materials above mentioned are found to answer well in practice, and the use for the anodes and cathodes of metallic salts of two degrees of oxidation facilitates formation or reduction into a condition adapted for speedy polarisation by electric currents. Although the above proportions and materials are best adapted to ensure rapid formation, any suitable framework or binding agent may be used in combination with the above mixtures or compounds. After the pulp and metal have been well mixed together in the presence of water, the compound or mixture is, whilst moist, spread or laid on one or both, preferably both, sides of a thin plate of lead platinum, or suitable material, to form a coating of about one-eighth of an inch thick." The number of the patent is 4809, 10th October, 1882.

Compass Deviatons.—Staff-Commander E. W. Creak, R.N., recently communicated a paper to the Royal Society "On the changes which take place in the deviations of the standard compass in the iron armour-plated, iron, and composite built ships of the Royal Navy on a considerable change of magnetic latitude." The general conclusions arrived at by the author are as follow:—1. A large proportion of the semicircular deviation is due to permanent magnetism in hard iron. 2. A large proportion of the semicircular deviation may be reduced to zero, or corrected for all magnetic latitudes, by fixing a hard steel bar magnet or magnets in the compass pillar, in opposition to, and of equal force to the forces producing that deviation. 3. A very small proportion of the semicircular deviation is due to sub-permanent magnetism, which diminishes slowly by lapse of time. 4. The sub-permanent magnetism produces deviation in the same direction as the permanent magnetism in hard iron, except when temporarily disturbed (1) by the ship's remaining in a constant position with respect to the magnetic meridian for several days, (2) by concussion, or (3) by both combined, when the disturbance is intensified. 5. To ascertain the full value of changes in the sub-permanent magnetism, observations should be taken immediately on the removal of the inducing cause. 6. In the usual place of the standard compass the deviation caused by transient vertical induction in soft iron is small, and of the same value (nearly) for ships of similar construction. 7. The preceding conclusions point to the conditions which should govern the selection of a suitable position for the standard compass with regard to surrounding iron in the ship.

A New Photometer.—A new and simple form of photometer has recently been designed by Mr. F. W. Hartley, of Millbank-street, Westminster. We take the following description of it from the *Journal of Gas Lighting*:—"It is intended for the easy measurement, in any situation, of the illuminating power of lights of any size, in any position, in the horizontal plane of the instrument or at an angle with it. The first instrument of this class has been made and used for the tests of burners now in progress in connection with the judging of the exhibits at the Crystal Palace. The examiners have found the arrangement so convenient that they now use it exclusively for the purpose with the Methven 2-candle screen. The latter standard, from its handiness, presents itself as the right one for a simple and, withal, exact appliance of this class, although, of course, any other is suitable. The apparatus consists of a table with two long slots in its surface. In one of these lies a movable scale, graduated in inches and tenths; and in the other slides the standard light by means of a winch. The light to be tested stands quite apart from the table, and according to its intensity may be 20, 30, 50, or 100 inches horizontally or diagonally from the screen when adjusted to zero of the scale. For all these determinate ranges, which give the operator the power of testing with a two-candle standard a light up to 555·6 candle-power, there are tables provided to obviate the necessity of calculation; although, as the readings are in linear measurements, the range of the instrument may be increased to any required extent. For angular measurements, Mr. Hartley has devised a scale for determining the hypothenuse, or the direct path of the light-rays to the photometer disc, which is a noteworthy addition to the handiness of the whole arrangement."

Self-Regulating Dynamos.—We take the following from Patent No. 4810, dated Oct. 10, 1882, and granted to Messrs. R. E. B. Crompton and Gisbert Kapp, which relates to their method of compound winding for dynamos:—"One method of carrying out this compound winding is to take a dynamo electric machine having an armature resistance of say 0·1 ohm, and wind on to its field magnets next to the core sufficient turns of No. 5 B.W.G. wire to give a resistance equal to that of the armature or 0·1 ohm or thereabouts and couple these coils in series circuit with the armature in the ordinary manner. Outside these coils we wind on sufficient ·057" wire to give a resistance of 20 ohms or from that to 30 ohms. We couple up this second winding of fine wire from brush to brush. Such an armature we prefer to drive at such speed that the electromotive force when the resistance of the external circuit is infinite will be about 65 volts. It will be found that if the external circuit be now closed through resistances varying from infinity down to 0·75 ohm, so that the current in the armature varies from two amperes up to 80 amperes, the electromotive force between terminals will remain nearly constant at the above named 65 volts. Moreover, that the magnet charge or extra current of the short length of low resistance coils will be so small that 40 or 50 lamps may be switched simultaneously out of the main circuit without producing any momentarily hurtful increase of current in one lamp left in circuit. This compound winding of the field magnets of dynamo electric machines has the further advantage of reducing sparking and wear of commutator and brushes to a minimum, as it always maintains a due proportion between the strength of the fixed magnetic field and the distorting influence of the induced field of the rotating armature."

H.M.S. "Himalaya."—This well-known troopship, which was lighted throughout with incandescent lamps by the Swan United Electric Light Company some six months ago, has just sailed on another outward voyage. Since the incandescent system was established on board her she has been to China and back, and traversed some of the hottest regions of the globe. It is satisfactory, therefore, to all interested in the electric light, and particularly the incandescent system, to learn that her officers were able on their return to send in to the Admiralty a most favourable report of the lighting. It was estimated that the lamps were in use for fully 1,000 hours, and this is probably well within the mark. The breakages only amounted to 25 lamps out of a total in use of 240. These figures speak for themselves. It is also very satisfactory, and affords evidence of good workmanship, to hear that, although a careful inspection of the whole installation was made on the ship's return from her four months'

Digitized by Google

voyage, no repairs or overhauling were found to be necessary. In connection with the above ship an interesting experiment was made just before she sailed on the 26th May. Experience in Egypt in the disembarkation of troops by the electric light has induced the Admiralty to consider the question of supplementing the interior lighting with deck lamps hung in the rigging. In order to retain as far as possible the simplicity of the system, it was determined to try a group of incandescent lamps in preference to an arc lamp. For this purpose two regulation ship's lanterns were fitted with eight 50 candle-power Swan lamps each. The result obtained exceeded all expectation, for though the actual rays of light were not, of course, as powerful as with an arc, the general decision was that, owing to the equal distribution of the incandescent system, it was a more thoroughly practical light to work by, and we understand that it is highly probable that a similar system will be adopted in future cases.

The Electric Light on Brooklyn Bridge.—The first experimental test of the electric light installation on Brooklyn Bridge was made on Saturday, 19th May, says the last issue of *The Electrical World*, which we have just received. Everything was found to be in excellent order and the system worked to perfection. The United States Electric Illuminating Company is to be congratulated on its success in carrying out this piece of electrical engineering. The 70 lights are divided into two distinct circuits of 35 lights each. There are two separate engines, one for each circuit. The lights are so distributed on each circuit that in the event of the stoppage of one engine the light produced by the lamps on the other circuit will be equally distributed over the whole bridge. Each engine will serve to work two 20-light dynamo electric machines connected in series, which will furnish the current necessary for each circuit. The machines differ from the ordinary arc light machines in the fact that their magnetic fields are wound in derivation. The total length of the leading wires is said to be 30,000ft. The wire used is No. 3 of copper, braided, covered with kerite and painted so as to be absolutely proof against short circuits from contacts at any point with ironwork, and so that they may be protected effectually from water. The conductors are sunk in pipes and masonry along the approaches, and are secreted in wooden boxes along the bridgeway. There are also over 1,000ft. of small wire for the four station lamps. The lamps are all double, so as to accommodate two sets of carbons, and this will give them a capacity for burning in winter from 4:30 p.m. to 6 a.m. Their light-giving intensity is 2,000 candles (nominal). The lamps are suitably protected by the wire netted globes, and are fastened to ornamental bars projecting from iron posts suitably provided for them. It is said that besides the continuous circuit there is a wire that goes to each lamp separately, and which is used for the purpose of lighting and extinguishing the lights.

Secondary Batteries and Electric Lighting.—Mr. Lane-Fox's Patent.—On Friday, the 1st inst., before the Solicitor-General, Mr. Lane-Fox made application for leave to disclaim from his patent for the employment of secondary batteries in electric lighting, which is dated 9th October, 1878, all the claims originally made by him except that which covers the employment of secondary batteries in combination with parallel arc distribution as described in his specification. His application was opposed by the Swan United Electric Light Company, Messrs. R. E. Crompton and Co., and the British Electric Light Company upon various grounds, among which were that the invention to which Mr. Lane-Fox wished to limit his patent by the proposed disclaimer was wanting in novelty, that it was not the proper subject for a patent, that it was not sufficiently described in his provisional specification, and that the proposed disclaimer would alter the character of the patent. Mr. Webster, Q.C., and Mr. Moulton (instructed by Messrs. Grover and Humphreys, solicitors, and Mr. J. C. Mewburn, patent agent) appeared for Mr. Lane-Fox in support of the disclaimer. Mr. Aston, Q.C., and M. Chadwyck Healey (instructed by Mr. J. H. Johnson, solicitor) appeared for the Swan United Company; Mr. Aston, Q.C., and Mr. Phipson Beale (instructed by Messrs. Brooks and Son, patent agents) for Messrs. R. E. Crompton and Co., and Mr. E. Carpmael (instructed by Messrs. Wilson, Bristows, and Carpmael, solicitors) for the British Electric Light Company. Evidence in support of the disclaimer was given by Mr. Lane-Fox, the patentee, Professor Fleeming Jenkin, F.R.S., Professor Silvanus Thompson, D.Sc., and Mr. R. Sabine, and in support of the several oppositions by Mr. J. W. Swan, Mr. R. E. Crompton, Dr. Hopkinson, F.R.S., Mr. W. H. Preece, F.R.S., Professor Ayrton, F.R.S., Professor Oliver Lodge, Mr. D. G. Fitz-Gerald, and Hon. R. Brougham. After a long hearing the Solicitor-General decided to grant Mr. Lane-Fox's application for leave to disclaim. The claim under this patent will, therefore, be for the employment, as described in the specification, of secondary batteries as reservoirs of electricity in combination with a mode or system of distribution such as is therein explained.

Electric Lighting for Aberdeen.—At a meeting of the Town Council of Aberdeen, held on Monday last, considerable discussion arose on the provisional order that the council has applied for. It appeared from the statement of the Lord Provost to the meeting that the council applied for a provisional order some months ago, but that the Board of Trade would not sanction it, and sent down a model order embodying the clauses and conditions that they would be prepared to sanction. Not having time to consider this model order at a full meeting, the council sent a deputation to the Board of Trade, to lay their objections to it before Mr. Chamberlain. The result of their interview with this gentleman was the drawing up of the following amendments to the order which the Lord Provost asked the council to pass These were (1.) That no maximum price shall be fixed in the order, but that the undertakers shall be required to supply electricity at the cost of its manufacture, including therein charges for interest and for sinking and reserve funds, &c., in terms of the draft clause submitted by them to the Board of Trade. (2). That before the undertakers are required to supply any part of the compulsory area in schedule A a requisition signed by the owners and occupiers of one-fourth of the premises along a street or part of a street within such area shall be served on them, and that the owners and occupiers signing such a requisition, or some of them, shall be bound to take a supply of electricity for three years to the extent and giving security as in Section 23 of the proposed order. If the Board of Trade would not give effect to those amendments, then, the Lord Provost said, the Town Council would withdraw their order, and content themselves with watching the Brush Company, who have also applied for an order. A discussion arose on the Lord Provost's statement, in which everyone agreed that it was not quite right that the whole community should be taxed in order that a section of them should enjoy the benefit of the electric light. In the end a motion to the effect that the council was prepared to accept the provisional order if the above-mentioned amendments were given effect to was passed by 17 to 4. If the Board of Trade do not comply with the council's request, then the order will not be proceeded with.

Digitized by Google

ELEMENTARY ELECTRICITY.—XI.

(CONTINUED FROM PAGE 57.)

In 1843 Prince Louis Napoleon, then a prisoner, writing to Arago, described two forms of battery in which only one metal was employed, so that there was nowhere a contact of dissimilar metals. The first consisted of a copper plate immersed in dilute nitric acid (which acts strongly on the copper), contained in a porous cell. The porous cell was placed in a jar containing dilute sulphuric acid in which was immersed a second copper plate. On connecting the plates with a galvanometer, a current flowed through the galvanometer from the plate immersed in the sulphuric acid to that immersed in the nitric acid. With a battery consisting of two of these cells he decomposed potassic iodide and cupric sulphate. The second battery consisted of two zinc plates, one immersed in dilute sulphuric acid contained in a porous pot, and the other in tepid water in a vessel surrounding the porous pot. This battery produced effects similar to that just described.

Napoleon then attempted to reverse "the usual order of the metals" (*i.e.*, Volta's contact series). He placed a copper plate in dilute nitric acid contained in a porous jar, while a plate of zinc was placed in pure (?) water surrounding the porous jar. On connecting the metals a current flowed from the zinc to the copper through the wire. These experiments alone seem sufficient to condemn the contact theory, as held by those who maintain that the electromotive force of a battery is due simply to the contact of dissimilar metals. More recently several other forms of battery have been devised, in which there is no contact of dissimilar metals. Napoleon complained that he was unable to measure the electromotive force of his batteries, as the iron bars of his prison interfered with his galvanometers.

If we suppose that when zinc and sulphuric acid are in contact and in equilibrium the potential of the acid is very much greater than that of the zinc, and similarly in the case of copper and sulphuric acid, the potential of the acid is much greater than that of the copper, but the difference in the case of the copper is less than in the case of the zinc, while we further suppose, as indicated by the Peltier effect, that there is no sensible difference of potential between copper and zinc when in contact, we can explain the action of the voltaic cell.

Suppose a plate of copper and a plate of zinc to be immersed in sulphuric acid, but no contact to be made between the plates. Then the acid must be at the same potential throughout, or it could not be in electrical equilibrium. Hence, since the difference of potential between the acid and the zinc is greater than that between the acid and the copper, the potential of the zinc plate will be lower than that of the copper and a quadrant electrometer would be capable of measuring this difference of potential which will be the electromotive force of the cell. If the copper and zinc are connected by a wire a current will flow from the copper to the zinc along the wire, lowering the potential of the copper and raising that of the zinc, so that the equilibrium between the metals and the acid becomes disturbed, electricity flows from the zinc to the acid and from the acid to the copper, so that the potential of the acid near the zinc is raised above that of the acid near the copper, and a current therefore flows through the acid from the zinc to the copper, thus completing the circuit.

If a plate of copper and a plate of zinc be connected together, and the free end of the copper plate dipped into one vessel of dilute sulphuric acid and the free end of the zinc plate into another vessel of the same liquid, the acid into which the zinc is dipped will be at a higher potential than that into which the copper is dipped. If now a connection is made between the two vessels of acid, by inverting a syphon filled with acid so that one leg is in one vessel and the other in the other, electricity must flow from the acid in the vessel in which the zinc dips to that in the other vessel, the equilibrium will be disturbed and a continuous current will flow through the circuit as before.

In the frictional electric machines, in the Voss and Holtz machines, in the replenisher and electrophorus the electrical energy developed is derived from the work done by the agent in overcoming the electrical attractions and keeping the machine in motion, or, in the case of the electrophorus, in raising the carrier plate in opposition to the attraction of the electrified ebonite. In the case of a thermo-electric couple, as will be explained under the head of thermo-electricity, the energy of the current is derived from the heat absorbed at the hot junction on account of the Peltier effect, or absorbed as the current flows from hot to cold or cold to hot along the metals on account of the Thomson effect. In the Voltaic circuit the energy of the current is derived from the chemical action which takes place between the metals, or one of the metals, and the acid (or electrolyte). That the energy of the current in ordinary batteries is due to the solution of the zinc in the acid was shown by Dr. Joule, who determined the amount of heat developed by a pound of zinc in sulphuric acid. He then immersed a battery in a calorimeter, and determined the whole amount of heat developed for each pound of zinc dissolved when the wire through which the current flowed was wholly contained within the calorimeter. The amount of heat so obtained was the same as when the zinc was dissolved in the acid without the production of any current. On causing the current from the battery to pass out of the calorimeter and to flow through a wire immersed in a second calorimeter the heat developed in the battery for each pound of zinc dissolved was less than before, but the deficiency was exactly compensated by the heat developed by the current in the external wire, and communicated to the water of the second calorimeter. From these experiments it appears that when a battery is employed in sending a current the heat corresponding to the chemical action taking place in the battery is not wholly developed within the battery, but a portion of it is employed in making the current flow through the circuit, and is reconverted into heat wherever the current does work against resistance.

We have already spoken of the electromotive force of a battery, but have not yet formally defined it. The electromotive force between two points is the same as the difference of potential between them, and is measured by the number of units of work done by the electric forces on the unit of electricity in passing from the first point to the second. Thus, if the terminals of a battery are disconnected so that no current is passing, the electromotive force between its terminals is the same as the difference of potential between them, and is represented by the number of units of work which would be done on a unit of positive electricity in passing from the positive to the negative terminal. This is called the electromotive force of the battery when insulated. It can be measured by connecting the terminals of the battery with the quadrants of an electrometer.

When the terminals of a battery are connected so that a current is flowing, the electromotive force of the battery is measured by the number of units of work done by the electric forces on the unit of positive electricity as it passes once round the circuit. The electromotive force of the battery under these circumstances will not in general be the same as when the battery is insulated, on account of the polarisation produced by the current. The cause of this difference, and and the method of measuring the electromotive force of the battery under these circumstances will be explained later on. The letters E.M.F. are frequently used as an abbreviation for electromotive force.

Faraday showed that when a pound of zinc is dissolved in a battery a definite quantity of electricity passes round the circuit. This will be referred to again in speaking of Faraday's law of electro-chemical equivalents. The electromotive force of the battery is the number of units of work done on the unit of electricity in going round the circuit. Hence when a pound of zinc is dissolved in a single cell, the electrical work done is proportional to the E.M.F. of the cell, being equal to the product of this E.M.F., and the number of units of electricity which flow round the circuit for each pound of zinc dissolved, and which is the same for all batteries. Now it is clear that this work cannot exceed the energy developed by the whole amount of chemical action

Digitized by Google

which takes place in the cell in consequence of the solution of the pound of zinc. Thus the nature of the chemical action taking place in the cell fixes a superior limit to the E.M.F. obtainable therefrom. For example, if zinc is dissolved and free hydrogen liberated, the work done in the cell is that due to the combination of zinc with sulphion, (SO_4) diminished by the energy absorbed in liberating the equivalent of hydrogen from the sulphuric acid. If instead of liberating the hydrogen as free gas it is allowed to combine with oxygen (*i.e.*, burnt) within the battery, the work done by the combination of the zinc with the sulphion will not have to be diminished by so large a quantity, and the E.M.F. of the cell may be considerably increased. Thus, in Grove's cell, in which the liberated hydrogen is burnt at the expense of the oxygen of nitric acid, and in the "bichromate battery" in which the hydrogen combines with the oxygen of potassic bichromate, the E.M.F. is greater than that which would be developed if the same plates (zinc and platinum or zinc and carbon) were simply plunged in dilute sulphuric acid. These batteries will shortly be described, but before entering into a detailed description of them we must study some of the properties of the electric current, and the conditions upon which its magnitude depends. We shall then be in a position to state the objects which must be secured in a battery, that it may be suitable for any given purpose, and to see how and to what extent these conditions are fulfilled in the several batteries which we shall consider.

Electromotive force has already been defined. This may be regarded as that which produces the flow of electricity which constitutes a current. A current in a conductor is measured by the number of units of electricity which flow across any transverse section of the conductor in a second, and this is sufficient to completely define the strength of the current, just as a current of water may be measured by the number of gallons of water passing any transverse section of the conduit in a second. But, in the case of the steady flow of water, a given "head" of water will not be able to produce more than a certain current in a given pipe, and this current will depend on the length and section of the pipe, and on the comparative roughness or smoothness of its internal surface. In the same way a given electromotive force will not produce more than a certain electric current in a given circuit. The property of the circuit which limits the amount of current produced by a given electromotive force is called the *resistance* of the circuit. If a circuit could be found having no resistance, a finite electromotive force would produce in it an infinite current, and since the number of units of work done on each unit of electricity in going round the circuit is equal to the measure of the electromotive force, the amount of work done in a second by a finite electromotive force sending an infinite current would be infinite. Hence we have the following definition of resistance :—

DEF.—The resistance of a conductor is that property in virtue of which a finite electromotive force is incapable of doing more than a finite amount of work in a second in sending electricity through the conductor.

The definition of the *measure* of the resistance of a conductor, involving, as it does, the relation between the electromotive force between the extremities of a conductor or around a closed circuit, and the current produced therein is involved in the statement of Ohm's law. This definition, together with the actual *law implied* in the statement, will be considered in the next paper.

(TO BE CONTINUED.)

ELECTRIC LIGHTING AND THE ITALIAN ADMIRALTY.—A contemporary says that a trial of electric light was recently made on board the vessel, "Custozza," before the officials of the Italian Admiralty and a special commission, with good results. The installation was carried out by Messrs. Braun and Heider, of Pola, the machines and apparatus being supplied by Messrs. Ganz and Co., of Pesth.

SOME ELECTROSTATIC AND MAGNETIC RELATIONS.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 55.)

18. What is, however, of greater importance than the mere symbolical identity of the operations is the physical interpretation that may be assigned to the different kinds of space variation. Operating upon an arbitrary vector function we obtain the scalar convergence and the vector curl; thus from magnetic force we obtain the density of magnetism and of current. That is to say, there are certain invariable relations between the space-variation of the magnetic force about any point, and the density of magnetism and of current at that point, which are most comprehensively stated in saying that the amount of magnetism within any space, which may be large or small, equals the whole amount of magnetic force leaving the space through its surface, and that the total current passing through any closed curve equals the line-integral, or the circulation of the magnetic force along the curve in making one complete circuit. But instead of such an abstraction as magnetic force, let us suppose that our vector function is of the simplest conceivable type, that it represents the continuous displacements of the particles of a continuous mass. Selecting any particle, the straight line drawn from its original to its final position is its displacement. The displacements of all the points constitute the vector system, or, expressed mathematically, the vector function. In estimating the space variation of the displacement, we have to examine the manner in which it varies in the neighbourhood of any particle O. In the first place the particle O with the surrounding particles may be displaced as a whole, a bodily translation in fact. This we disregard in considering the relative displacements, that is, we regard O as fixed. In the next place, the group of particles surrounding O may occupy a greater or less volume in the strained than in the unstrained state, *i.e.*, there may be expansion or compression. The expansion is estimated by finding the additional volume occupied in the strained state by the particles which occupied the unit volume in the unstrained state, and this is plainly to be done by finding the whole displacement outward through the surface of the unit volume; hence "divergence" in general, when applied to the special case of displacements, has the same meaning as the cubical expansion.

Again, the group of particles surrounding O may, during the act of displacement, suffer not merely the translation and the expansion, if any, but a rotation through a definite angle about a definite axis. Going back to the figure, let the displacements X be all perpendicular to the paper, say downward, and consider the variation of X about the point O. If O and the particles surrounding it are equally displaced, the matter in the plane of the paper about O is merely transferred bodily, remaining in a plane parallel to the paper; but should there be a greater displacement on one side than on the other, there will be rotation as well. Thus, if O R as before be the direction in which the displacement increases fastest, O R′ perpendicular thereto is the axis of rotation of the matter about O. Now O R′ represented our vector curl; consequently, interpreted for parallel displacements, the curl is the vector axis of rotation, and by elementary considerations its amount is twice the (small) angle of rotation. Hence, remembering the manner of composition of rotations, we see that the curl of the displacement function is a vector showing by its direction the resultant axis of rotation of the matter surrounding any point, and by its length twice the angle of rotation.

Also, it results from the analysis of the most general continuous displacements of a collection of particles, that the particles which originally occupied a small sphere with centre at O in the unstrained state occupy an ellipsoid after the displacements. The principal axes of the ellipsoid always correspond to a set of three rectangular lines in the original sphere, but there are two distinct cases. The three lines in the sphere may, as the sphere is turned into the ellipsoid, keep their directions unchanged, in which case the strain is

Digitized by Google

pure, and may be produced by three rectangular compressions or elongations acting in directions parallel to the three lines. In the second case the three lines in the sphere do not keep their directions unchanged during the displacement, but are rotated as a whole about some axis. This is a rotational strain, and there is one definite manner of decomposing an arbitrary strain into the simultaneous effects of a pure strain and a rotation.

Thus, corresponding to divergence and curl, we have expansion and rotation. The condition of no divergence means, in the case of displacements, that the strain ellipsoid has the same volume as the corresponding sphere, and the condition of no curl implies that the strain is pure, or unaccompanied by rotation.

We have similar results when we consider not the displacements, but their rates of increase, *i.e.*, the velocities of the particles. Thus, the motion of a fluid may be rotational or irrotational at any place; in the latter case the curl of the velocity is *nil*, in the former its value is twice the angular velocity.

19. Electric current and its related quantities are all characterised by the absence of divergence. Their distributions are therefore similar to possible states of displacement of the particles of an incompressible solid, or of the instantaneous velocity of an incompressible liquid. There is also a common characteristic, that having no divergence anywhere they have necessarily curl somewhere, a property essentially connected with the existence of *closed* lines (of force, current, &c.). Let us suppose that we have a field of magnetic force, B_1, due to currents only, and that the force actually produces a small displacement in the medium where it acts, of amount proportional to the strength of force. A state of strain would be set up. In space unoccupied by current, curl $B_1 = C_1 = 0$, and the strain is pure. But where there is current, curl $B_1 = C_1$ is finite, and the strain is rotational, its axis is the direction of C_1, and the angle of rotation $\frac{1}{2} C_1$ in amount. In both cases, either within or without the current, div. $B_1 = 0$, or there is no expansion accompanying the strain.

The existence of the rotation (with the above assumption of displacement in the direction of B_1) is easily recognised in the case of a straight current. Let the wire be of circular section. The lines of force are circles in planes perpendicular to the axis, centred thereon. The strength of force increases from *nil* at the axis regularly to a maximum at the surface of the wire, being, anywhere between, proportional to the distance from the axis. If we then take a thin slice of the wire bounded by two parallel planes perpendicular to the axis, and displace its parts through very short distances proportional to and in the direction of the magnetic force at any place, the result will be a rotation of the slice *en masse* about the axis, as a wheel for example. It is easily seen also that the supposed displacements produce relative rotation of the same angular amount of any two points in the slice, and that besides the motion of translation as a whole of the particles surrounding a given point, there is the definite rotation about a line parallel to the axis of the wire. The rotations are equal, because we have tacitly assumed the current density to be uniform throughout the section of the wire. Outside the wire, however, the strength of force falls off, varying inversely as the distance from the axis. This distribution of force makes curl $B_1 = 0$, and the corresponding strain at any place where small displacements are produced by the force is unaccompanied by rotation, or the displacement is differentially irrotational. [We have used the word "strain" to include the case of mere rotation without distortion.]

20. But by far the most interesting analogue is that presented by the motion of a perfect incompressible liquid. Let it fill all space (since the magnetic force of our rectilinear current extends without limit), and replace lines of force by lines of motion of the liquid, its velocity to everywhere correspond to the strength of magnetic force. We have then a case of vortex motion. The liquid within the cylindrical space corresponding to the wire is rotating, every particle of it, with the same angular velocity. The motion of the liquid outside the vortex, however, although the lines of motion are circles about the vortex, is differentially irrotational—*i.e.*, particles which at a given moment occupy a very small sphere about a given point, at a very short time after occupy an ellipsoid of the same volume without rotation from one to the other. We might, from our knowledge of the relations between magnetic force and current, deduce some of the remarkable properties of vortex motion, so far as they do not involve the dynamics of the subject—*i.e.*, merely characteristics essentially connected with the motion. Current direction corresponds to the axis of a vortex, current density to twice the angular velocity; vortex lines and tubes, analogous to current lines and tubes, are always re-entrant; the line-integral of magnetic force about a current measuring the amount of current corresponds to the circulation of liquid about a vortex being proportional to the angular velocity of the latter, &c. But, not to go into details, we will merely note, further, the analogue of the identity $\frac{1}{2}\Sigma B_1^2 = \frac{1}{2}\Sigma \overline{A_1 C_1}$ (p. 391 ante). Here, B_1 being the magnetic force of current C_1, whose v.-potential is A_1, we have two expressions for the quantity that there is reason to believe is the kinetic energy of the system of magnetic force. Now, let B_1 be the velocity of a perfect liquid of unit density, then $\frac{1}{2} \Sigma B_1^2$ is really the kinetic energy of the whole motion (sum of mass of each elementary portion × $\frac{1}{2}$ square of its velocity). We have then the remarkable result that the kinetic energy of the moving liquid can be expressed in terms of its angular velocity in those places where the motion is rotational, and of the corresponding v.-potential. Further, since if $C_1 = 0$ everywhere, making $\Sigma \overline{A_1 C_1} = 0$, it follows that $\Sigma B_1^2 = 0$, which (being the sum of squares) involves $B_1 = 0$ everywhere. That is to say, if there is no rotation there can be no motion of the liquid. Hence, if the liquid fills all space, its motion, whatever it be, cannot be everywhere irrotational. When, however, the liquid is bounded, as by the surfaces of immersed solids, the motion of the liquid *may* be everywhere irrotational in itself. If so, the rotation is to be sought at the bounding surfaces, and there it will be found, being represented by the difference of the tangential motion of the liquid passing the surface of a solid and of the solid itself at the same place. Or we may reduce this to the former case by imagining the solid to (momentarily) become liquid like the rest, whilst the new liquid has the motion of the solid at the moment considered. There is now continuity of the normal components, and in general discontinuity of the tangential components of the motion of the liquid just within and just without the surface, which was that of the solid before it was melted, and, consequently, differential rotation at the surface. The latter, therefore, constitutes a vortex sheet, analogous to a current sheet, and the vortices are distributed just as the current would be in the current sheet, which would produce a field of magnetic force exactly corresponding to the actual state of motion of the liquid at the time.

21. A simple example is that of a spherical solid set in motion in a perfect liquid originally at rest. Let its velocity at any time be V parallel to *s*. The motion of the liquid exactly corresponds to the external magnetic force of the system of surface current over the sphere which would produce an internal field corresponding to the given internal motion, *i.e.*, a uniform field of strength V parallel to *s*. To find this system, we may notice that the curl of the magnetic force given, the internal uniform field, is purely superficial, of amount $V \sin \theta$ at any part of the surface whose angular distance is θ from the pole or most forward point of the sphere in motion. A system of circular currents over the surface, of strength $V \sin \theta$, with positive motion about the axis *s*, will be easily found to give a uniform internal field parallel to *s*, but only of strength $\frac{2}{3}$ V. Consequently, if we make the strength of current $\frac{3}{2} V \sin \theta$ we get the required internal field of strength V, and the corresponding external field will represent the liquid motion when we translate V as velocity.

Digitized by Google

The added current corresponds to the external surface curl, of magnetic force or of velocity as the case may be. The external v.-potential of the surface current is $\frac{1}{2}\frac{Va^3}{r^2}\sin\theta$ at distance r directed perpendicular to r and s, the lines of v.-potential thus being also circles about s in planes normal to s. At the surface it becomes $\frac{1}{2}Va\sin\theta$, if a be the radius of the sphere, and coinciding in direction with the current. Hence we may easily find the energy, viz.:—

$$\frac{1}{2}\Sigma\overline{AC} = \frac{1}{2}\iint\frac{1}{2}Va\sin\theta.\frac{3}{2}V\sin\theta.\,a^2\,d\mu d\phi = V^2\pi a^3.$$

Of this $\frac{1}{3}$ is external, $\frac{2}{3}$ internal, as we may conclude from our having obtained twice as great internal as external surface curl, agreeing with the well known result that the kinetic energy of the liquid is one half that of the solid sphere which moves it if it has the same density. $V^2\pi a^3$ is in fact the whole energy in the electro-magnetic case, and also the whole energy in the case of the moving liquid, including that of the sphere of same density. The external magnetic force, or velocity, is the curl of the above v.-potential $\frac{1}{2}V\frac{a^3}{r^2}\sin\theta$. The scalar potential, on the other hand, is $\frac{1}{2}V\frac{a^3}{r^2}\cos\theta$, and its space-variation gives the magnetic force or the velocity at any point. This scalar potential is that of the magnet, which would give the same external force. It may be got by substituting a plane magnetic shell for each circular current. The whole collection of shells constitutes a sphere magnetised to intensity $\frac{3}{2}V$ parallel to s.

22. The other kind of magnetic force, B_2 above, arising from magnetism, possesses just the same characteristics as B_1 arising from currents, as regards the space external to the magnetised matter. In fact, given a space in which there is a given distribution of force, but quite devoid of current or of magnetisation, and given no knowledge of anything outside the space, it is impossible to say what the origin of the force is, whether magnetisation or current. No necessary distinction can be drawn under the mentioned circumstances. The sources external to the space considered might be either currents or magnetism. The lines of force of B_2, however, in a complete field, as well as in the incomplete field above, are unclosed, and hence arise important differences in the mathematical treatment. But this idea of magnetic force being due to magnetic matter, the residual or unneutralised polarity of the magnetisation, whilst perfectly accounting for the external force, is in all probability entirely erroneous as regards the force within a magnet, and so may be here dismissed, and the more complete theory of internal force will be considered later.

(TO BE CONTINUED.)

EXPERIMENTS WITH SECONDARY BATTERIES.

In the *Electrotechnische Zeitschrift* of May there is an interesting description of experiments on the charging and discharging of storage cells by Herr v. W. Hallwachs, which deserves attention both on account of the pains bestowed upon the observations of the conditions and of the conclusions at which the author has arrived, not always in accordance with current ideas. The elements used were four in number. Nos. I. and IV. were made by Herr Otto Schulze, and consist of a series of lead plates, of which the even numbers are connected together metallically, and also the odd numbers. No. I had five plates, on which 1kg. of red lead was spread, the plates being 20cm. high and 10cm. wide. Its weight with acid was 8·1kg. No. IV. had thirty plates, which were roughened and then spread with flowers of sulphur and warmed so that a coat of sulphide of lead was formed upon them. The weight of the element was 10·5kg. No. II. was an element of Tommasi, composed of two square frames 30 by 30cm., made of square lead rods, the space being filled with horizontal lead strips $\frac{3}{10}$mm. thick and 15mm. wide, packed close together. This element weighed 21·4kg. No. III. was an element of Bréguet, made of two sheets of lead separated by strips of caoutchouc, and rolled up into a cylindrical form and placed in a glass cylinder. It weighed 4·9kg. Both No. II. and No. III. were prepared by the Planté method. The fluid employed was sulphuric acid diluted with ten volumes of water.

The following table gives the result of the experiments:—

Charge.					Discharge.				
Element.	No. of Experiments.	T in Hours	(J_0)	L_e in 10^3 V.A.S.	r	t in Minutes.	l in 10^3 V.A.S.	(i_0)	N
I	2	10	6	800	0,22	123	224	10,1	0.28

J_0 represents the mean value of the charging current.
i_0 „ „ „ discharging current
T „ time of charging in hours.
t „ „ discharging in minutes.
L_e is the electrical work done against the E.M.F. of the cell in charging $\left\{=\int JE\,dT\right\}$ in terms of units, each of which is 1,000 B.A. units.
l = electrical work given out by the cell in discharging $\left\{=\int i.e.\,dt\right\}$ in the same units.
N is the ratio of l to L_e.
r is the external resistance when discharging.

The following are among the conclusions which the author draws from his experiments:—

On first beginning to charge the element the E.M.F. of the element increases very rapidly, at a rate depending on the value of the current, until it reaches a value varying from 2 to 2·4 volts. Then if the current is maintained constant the increase goes on slowly, and the author has not succeeded in reaching a point where it is a maximum under these conditions, though if the value of the current diminishes the E.M.F. of the element may fall. Fig. 1 illustrates this increase. Fig. 2 represents discharge. At the beginning the E.M.F. is about 2 volts. As the store of energy diminishes the E.M.F. falls, at first slowly, then more quickly, and afterwards very slowly, but never quite to zero.

The following experiments made with No. I. element show the variation of the E.M.F. with the strength of the charging current:—

Experiment.	J_0.	T.	E_e.
8	1·1	4	1·95
6	3·9	4	2·19
16	4·	4	2·27
14	6·7	1	2·20
13	7·4	7	2·33
7	17·1	4	2·46

Digitized by Google

Then J_o E_o are mean values respectively of the current, and the E.M.F. of the element.

Experiment 14 shows clearly the effect on E_o of the duration of the period of charging.

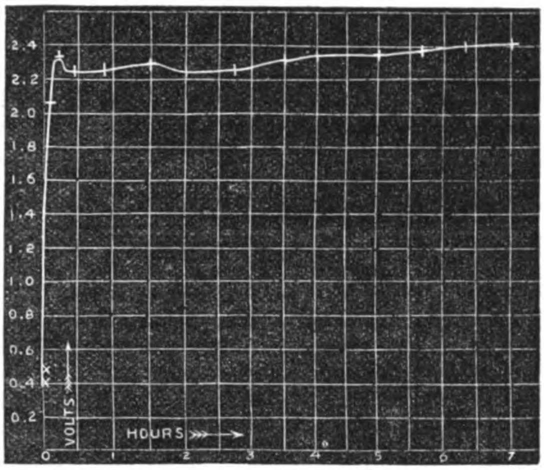

FIG. 1.—Showing increase of E.M.F. during charge.

The resistance of an element during charging sinks to a constant value, in the case of the elements used, as follows:—

Element I. ·009. to ·014 ohm.
„ II. ·020 to ·025 „
„ III. ·015 „
„ IV. ·015 „

During discharge the resistance is at first constant, but begins to increase proportionately to the lapse of time at the point where the E.M.F. begins to fall quickly.

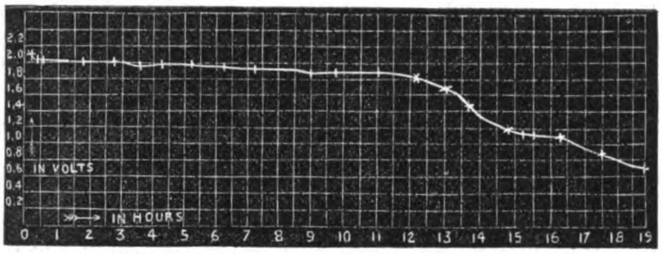

FIG. 2.—Showing fall of E.M.F. during discharge.

Figure 3 shows these effects.

The following experiments with No. I. element show the effect upon the efficiency (N) of its previous history and employment:—

Experiment.	N.	T.	J_o.	r.
6	·21	4	3·9	·138
16	·47	4	4	·135
20	·48	4	4	·135
22	·28	4	4·2	·118

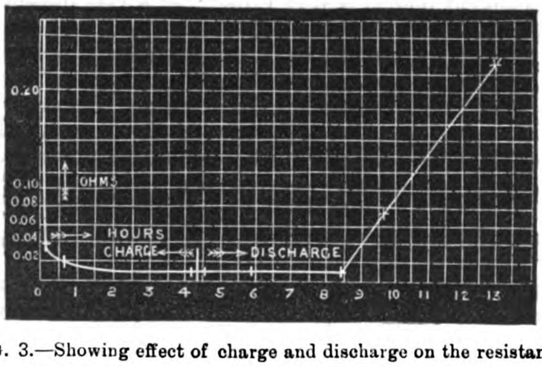

FIG. 3.—Showing effect of charge and discharge on the resistance.

Before Experiment 6 the element had been used for affording light for about two months, then after a month's rest had been charged and discharged some ten times. Between 6 and 16 it had been charged and discharged about twenty times, between 16 and 20 about four times, and between 20 and 22 twenty-seven times, with a pause of 12 hours after each charging. At the next charge the element broke up. The value of the charging current may be observed to affect the value of N, the efficiency, and in such a way that there is a certain value of the current for which the efficiency is a maximum. This value is between 4 and 11 amperes, but is not determined.

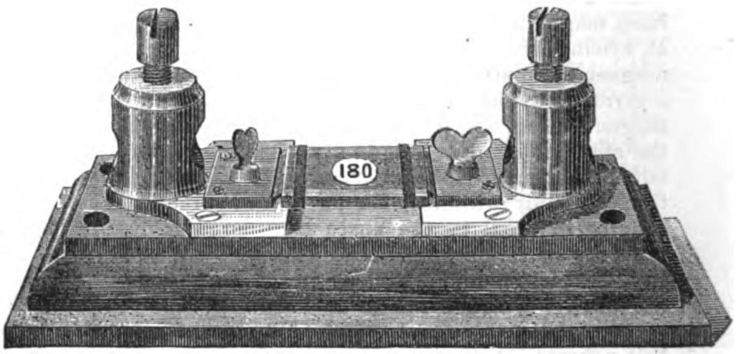
A long pause ensuing between the charge and discharge has a bad effect upon the efficiency, as may be gathered by comparing Experiments 10 and 11, in the first of which an interval of 14 hours' rest was allowed to elapse, during which the plates were removed from the liquid. The values of N in these two cases were ·10 and ·37 respectively.

The best value of N obtained was ·50, in Experiment 15. The value of the charging current was 8·3 amperes. In Experiment 13 the most work was obtained from the element, viz., 175,000 volt ampere seconds. This would be about 3,000 kilogrammeters per kilogram of electrodes.

HEDGES' PATENT CUT OUTS WITH FUSIBLE SAFETY PLUGS.

The use of safety plugs in all installations of the incandescent electric light is now a recognised necessity. Much annoyance has, however, been experienced by electricians on account of the frequent rupture of the piece of lead wire or bar of alloy, which has hitherto been used as the safety fuse.

Experiments show that any alloy of tin with lead or copper is useless on account of the rapid deterioration of the metal caused by the passage of the electric current, besides having the objection, common to all metals employed in a bar form, that, on account of inequality of the temperature, the moment of rupture is accompanied with noise and the scattering of the molten metal.



In Hedges' cut outs for sizes to take a current above 20 amperes the fuse consists of thin foils of special alloy, which is known as Albo metal, the area of the foils and the number being in proportion to the currents to be carried. The foils are separated and thoroughly insulated from each other by mica plates, so that the current is divided through the whole number, and the rupture takes place through the centre. The mica, not being affected, can be used over again.

For currents under 20 amperes a special cut out is designed, in which the foil is wrapped round a piece of mica and connected on each side to the two terminals, so that it can instantly be replaced, whereas, with lead wire, making the connection is a matter of difficulty. This form of fuse takes little space, and can be easily introduced into a small switch.

These foils have been in practical use at the new Law Courts since their opening, and some which have been employed the whole of the time show no deterioration. They can be safely worked within 10 per cent. of their melting point, but where the current is likely to be irregular it is better to allow a larger margin.

For secondary batteries they are extremely useful to prevent reversal of the current when the dynamos are stopped.

The cut-out illustrated above is supposed to contain a fuse which will melt with a current of 180 amperes. Mr. Killingworth Hedges of 25, Queen Anne's-gate, Westminster, is the designer of these cut outs.

A TENDER FOR ELECTRIC LIGHTING.

We herewith give an estimate which has been furnished to the Vestry of St. Mary, Newington, by the Electric Carbon, Storage, and Apparatus Manufacturing Co. of Scotland for an installation of incandescent lamps. The Vestry have also prepared an estimate, which we give below :—

Company's Estimate for an Installation of

6,000 incandescent lamps of 16 candle-power.
50 do. 50 do.
Making a total candle-power of 98,500.
For which would be required 500 effective horse-power.

	£	s.	d.
Compound steam engines, with boilers, complete...	£3,600	0	0
Fixing ditto	200	0	0
Self-regulating safety dynamo machines complete.	3,000	0	0
Fixing ditto	50	0	0
Shafting and belting	150	0	0
Engine house	500	0	0
Altering present street lamps to suit electric light.	100	0	0
Main and branch leads, as shown on plan, with allowance for future extension to St. George's Church with Dr. Higgs's patent earth plate	2,000	0	0
Contingencies	500	0	0
	£10,140	0	0

Cost of Maintenance (Annual).

	£	s.	d.
1,690 tons of coal at 20s.	£1,690	0	0
1 manager	180	0	0
1 assistant	104	0	0
2 engine drivers at 30s.	156	0	0
2 engine stokers at 20s.	104	0	0
2 boys at 5s.	26	0	0
Oil, waste, water, &c.	300	0	0
	£2,560	0	0

Revenue.

	£	s.	d.
From 5,000 lamps at gas rate	£3,662	0	0
,, depôt gas account	160	0	0
,, public streets	205	0	0
Profit on sale of lamps, at 6d. each, say 6,000	150	0	0
	£4,177	0	0

	£	s.	d.
Annual revenue	£4,177	0	0
,, expenditure	2,560	0	0
Balance to carry forward to redemption of debt*	£1,617	0	0

Leith, May 16, 1883.

Dear Sir: In handing you this estimate, I am not actuated by primary motives of personal profit, but more to enable you to convince your ratepayers and the vestry of the enormous advantages they would derive from the adoption of a good system of electric lighting. I have read with pleasure your report and the remarks therein of Dr. Siemens and of Mr. Lane-Fox, both of whom are authorities of considerable experience, and their remarks deserve due attention. I must, however, take exception to the statement by Mr. Lane-Fox, "that with good machinery a combustion of 1¾lb. of coal will yield one horse-power per hour." In practice, and with the best machinery, 2lb. to 2½lb. of good Cardiff coal is required to yield one horse-power per hour. This I have proved by long experience with the best class compound engines. Also, with an economical dynamo, such as the one invented by Dr. Higgs, 200 candle power may safely be calculated per indicated h.-p. Dr. Siemens's figures, as regards the comparative cost of electricity as against gas, are convincing to an ordinary observer; and the only thing that remains is to instil confidence into the minds of the public, and you will have their hearty support in your endeavours in the direction in which I am glad to see you are moving.

You will see from the estimate which I have the honour to submit to you that the initial cost of the whole

	£	s.	d.
plant is	£10,140	0	0
The annual expenditure	2,560	0	0
The annual income	4,177	0	0
Leaving a balance of	1,617	0	0

clear profit, which will enable you to pay off your loan in less than 15 years with ease. Moreover, the profits are likely to exceed the estimated amount, for while the expenditure will remain almost stationary, the revenue from lighting will increase until, within three or four years, the whole 6,000 lamps will be called for, thus adding £1,000 per annum to the revenue.

Profit may also be derived from rent of meters, sales of fittings, and also from the use of electricity as motive power for driving sewing machines, and other light work.

Another important factor is the accumulator, without which you should not attempt house lighting, for it is not reasonable to expect your customer to consume what he pays for immediately he gets it; but he should be able to store the electricity for use when required, and also be able to use it for other purposes than lighting. You will see that I have estimated for the use of an earth plate for the return current; but if you prefer to have return wires, the cost would be £1,500 more.

The figures quoted, although approximate, are yet as nearly exact as it is possible to get; being rather over than under what an actual estimate would be; but should your vestry favour me with instructions for another estimate when you are prepared to go to work, I shall be most happy to go fully into the matter and quote you exact figures.

In reference to the system of lighting which is likely to prove most economical, I would point out that Dr. Higgs's dynamo is the only self-regulating one, and is the one which will be generally used so soon as its merits become known, as it is apparent to the most dull of comprehension that no system can be so economical which is not self-regulating.

I am in position to say that my company can offer you terms and facilities such as no other company has yet entertained, and at the same time give a full guarantee relieving you of all risk of failure. I have pleasure in enclosing copy of the report made by a deputation from the Bootle Town Council, knowing that it will be of interest to you, as being testimony from an independent and unbiased source.

I have confidence in thinking that these figures will convince the most determined opponent of the new illuminary that, from a purely commercial point of view, it will repay the outlay with interest, and even if this were not the case, and the electric light proved to be, light for light, more expensive than gas, yet there are other considerations to take into account. Is it nothing to be free from the danger of explosion and fire; nothing to be free from the overbearing heat and poisonous fumes, and the constant flicker of gas; nothing to have the atmosphere of our homes once more pure and free from the smokiness of gas? I think these advantages far outweigh any question of £ s. d.; but when these advantages are coupled with economy, surely it can be only madness that would refuse to discard the conservatism that would poison our bodies and burn our homes, rather than advance into the soft, soothing, and economical light of electricity.—Yours truly, John Evans Jackson,
Manager Elec. Carbon, &c., Co.

To L. J. Dunham, Esq., Walworth.

Vestry's Estimate for the Installation.

	£	s.	d.
Four 150 h.-p. engines, including boilers, setting and connections, at £9 per h.-p.	£5,400	0	0
For building shaft, &c.	1,000	0	0
Four dynamo machines, equal to 1,500 lights each, at 15s. per light	4,500	0	0
Fixing bands, connections and sundries	1,200	0	0
Cables, main electric lines and testing boxes, &c., from the depôt to the extreme limits of the compulsory district, provision being made to lay down a sufficient line to extend the supply to St. George's Church when required	6,000	0	0
Exchange of lamp posts, columns, and lanterns throughout the compulsory district, providing for new lamps and fittings for same	500	0	0
Lamps, columns, and necessary fittings for the street lighting between the depôt and the railway bridge, including necessary lamps and fittings for providing and supplying of electricity to the Vestry Hall and depôt	500	0	0
Contingencies	900	0	0
	£20,000	0	0

P.O. Orders to be made payable to JAMES GRAY, *at West Strand Post Office.*

ANSWERS TO CORRESPONDENTS.

AMATEUR.—*We do not think the author will go into the details of the construction of the instruments you mention. There are no books published of the kind you require. Culley's Handbook will give you a large amount of information as regards practical telegraphy, so will Preece and Sievewright's. Kempe's book on testing is the best of its kind, and we hear that a new edition will shortly appear. We think most of the information you seek has at various times been given in our columns.*

FINANCIAL PAPERS AND THE TELEPHONE COMPANIES.

We do not know that it is our duty to attempt to understand the reasoning of some of the financial papers when they discuss the commercial side of telephonic interests, but whilst caring little about the wire pulling for speculative purposes we must for the sake of *bonâ fide* investors declaim against unjust criticism. The general idea which seems to pervade the minds of the conductors of some of these financial papers is to slap away at everything electrical. It is sufficient that the market is depressed. It is known that great efforts are being made to keep going some large but wholly unsound concerns, but why a more judicious spirit in regard to other, to say the least, not wholly unsound concerns, should not prevail it is difficult to see. Admitting that speculators have reaped a harvest, admitting that they have well worked upon the credulity of the public, we must admit, nay, we will speak more strongly, we know, that some of the electrical companies are founded and are being worked upon the soundest business principles. Our opinion is that honest writers attempt to give an honest criticism, and that a financial paper which allows its columns to be one sided is never again to be trusted. Mistaken conclusions may always arise, but intentional inuendoes are far from creditable. We have had our attention called to a recent article upon telephone companies which we think is calculated to mislead many of its readers. Several companies are referred to, but we do not think sufficient care has been taken to show the vast difference between the one company and another. Each will be looked upon as equally bad; but is this so? Here is a sentence:—"The profit and loss of this company shows, *as we make it* (the italics are ours), a net loss in working of £2,960, whilst it is pleasant to think that the directors pocketed £1,500 in fees." Evidently the writer means to insinuate that if a concern does not pay the directors are not to be paid for their work. Apply this conclusion to newspaper editors, and see how they would like it. Is a company to prove a veritable Golconda, and must it pay upon its first real year of work? A more just criticism would have been one against the number of directors. Is it customary, too, with financial papers to put the whole cost of formation, building, &c., to one year's account, or is it usual to spread this cost over a number of years? In the balance-sheet criticised the "cost" is spread over a number of years; in the financial paper the "cost" is "lumped" into one year. It is admitted that this company—it is the Oriental Telephone Company, whose report appeared in our last issue, that we more especially refer to—is not in a present perilous position. This, however, is not the question before us, which, to put it plainly, is whether it is just to mix up criticisms and figures so as to tend to mislead the public. We have been slightly amused over the report of this company; in fact, most reports are to us amusing, it may perhaps be because of idiosyncrasies leading our thoughts more to the scientific than to the commercial. Directors are told that the dividend is made partially by a return of a premium paid by shareholders upon shares. No doubt; but do the shareholders expect the directors to do their best to make money when they can? Do they expect that if a premium is to be had the directors will refuse it because it adds to the profits? Then the financial papers criticise because something has been sold and increases the profit account. We would ask whether the directors are not elected to make a good bargain for the shareholders when they see a chance. We are politely told that a man with special knowledge, with special means of benefiting a company, should not be a director, because he is connected with another concern. Is it not a little too palpable that the logic of this argument is weak if put in other ways? Shall we say that Brown, Jones, or Robinson is ineligible to be a director of an iron works in New Zealand because he is a director of an iron works in Yorkshire? Why should not a man be a director of a "Cotton Mill Company" in Lancashire, of one in Bombay, and of one in the States? We do not pretend to see further through a brick wall than most people, and hence, we suppose, are unable to find a reason why such a state of things should not be. Put it another way. Jones purchases the patent of a bicycle. Is he ineligible to be a director of a bicycle company in New Zealand because he is a director in a bicycle manufacturing company in England, and hence interested in the promotion of such branch companies? The whole theory of this ineligibility is absurd unless the one company be by some means antagonistic to the other, and a a profit to the one means a loss to the other, or the director

Digitized by Google

has not the time to attend properly to the duties he has undertaken.

The report of the Oriental Company did not strike us in the same light as it seems to have been seen by our contemporary. We have long since expressed our views as to the prices paid for patent rights; but investors took little notice of the warnings of the scientific press. They have paid for their patent rights, and they know it, so why should they grumble now, when no objection was made at the time, when, in fact, the sole idea seemed to be to get the shares. Having sunk their money, the question is so to work as to get a fair return, and we fail to see where this question has not been constantly before the eyes of the directors of the company whose report we refer to. They have opened up exchanges at various places in the East, their list of subscribers is gradually extending, and there seems every prospect that a good profit will be made upon this exchange work. It takes time to establish exchanges, and at this early period of the company's work it is more the future prospects than present results that fixes attention, and according to the report these prospects are very good. We have preferred to deal more directly with the question of telephone companies than with electric light companies, because of the report and criticisms before us, and because we think that telephony must and will become as universal as telegraphy. There seems hardly any end to its development, and when a company has erected wires it does not much matter if science improves upon the instruments in use. The instruments used merely for the speaking or receiving are answerable for but a comparatively small part of the expense in connection with telephone exchanges, and the cost of replacing them with improved forms would not be excessive. The policy of directors should be closely watched, but they are surely justified in using every legitimate means to improve the company's position and to gain a dividend for the shareholders. The development of the exchanges is purely a question of time if the position of the exchanges has been wisely made, and the greater the number of exchanges the less becomes the dead weight of cost of patent rights. We again say that, while ready to acknowledge any praiseworthy efforts to show up rotten companies, we cannot support a policy that showers disparagement upon all alike. The market electrical is greatly depressed, and justly so, but surely that is a reason why financial advisers should endeavour to weigh justly every fact, and, where possible, to show the possibility, by judicious management, of a brighter future.

CORRESPONDENCE.

LECLANCHÉ CELLS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of May 26 that the writer of the articles on "Practical Telephony" strongly recommends the adoption of the prism form of the Leclanché cell, but I think that in practice the battery will not be found so good as the old form of Leclanché with the porous cell. Its chief virtue, of course, is its low internal resistance; but that is scarcely an advantage on a ringing circuit, while from the form of the india rubber band employed to bind the couple together local action is set up by impurities detached from the block and settling thereon, thus soon completely destroying the zinc. This form is dirtier to handle, with more risk of breakage, than the ordinary form, whilst from my observation it also "polarises" quicker on a short circuit.—Yours, &c.,

HAROLD DOWSON.

IMPROVEMENTS IN FAULT LOCALISATION TESTS BY FALL OF POTENTIAL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Permit me to occupy a space in your columns on a subject of great interest and greater practical value, one whose main features are already well known to the electrical world, but whose developments have not yet, it appears to me, received the attention they merit.

A method for localising a single fault in a single cable by observing the fall of potential through a part of it under certain conditions of electromotive force and resistance at one end, appears to have been invented by Mr. Latimer Clark comparatively early in the annals of electrical testing. This arrangement, now well known, is seen in the accompanying figure.

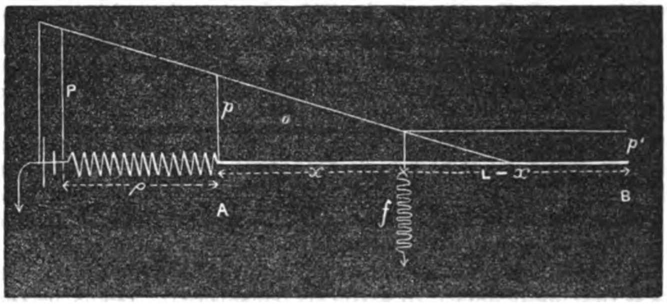

FIG. 1.

At the same moment the potentials P, p, and p' are observed, represented in the figure by ordinates erected on the circuit line at those points.

Then x, the distance of the fault from A in ohms

$$= \rho\left(\frac{p - p'}{P - p}\right) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad \text{(I.)}$$

This test, when carefully carried out, is most effective, and has often yielded very accurate results, but it has two weak points in its published form. These we will examine in detail.

It is generally found in practice that as regards measuring instruments at station A one is employed in preference to two. Firstly, it seldom happens that two electrometers are available at one station; or, if high resistances and galvanometers are employed in their stead, the necessary high resistances which can be collected seldom suffice for both galvanometers. Secondly, if even separate instruments for both potentials be forthcoming, it is well known that under the conditions of this test more error is likely to be introduced into the calculation in obtaining the relative value of their deflections than probably the dual observation will expel. One instrument is therefore placed in connection with the ends of the resistance ρ alternately, and time being always thus lost in the intervals, any change taking place during the test in the fault's resistance is only revealed in A's observation *per saltum*, while B's are continuous. Correction can, of course, be made for the want of continuity in A's readings, but only when the change taking place is steady, which is seldom quite the case. Consequently, error is introduced into the results through want of synchronism in the readings at each end.

The chief objection, however, is that the test is not a "null method." It has long been known, and the subject has lately received the attention of noted physicists, that far greater accuracy is attainable in electrical measurements when zero values have to be indicated than when a particular positive or negative value has to be observed. To this the accuracy of the Wheatstone bridge has well been ascribed. In other words, it seems that the conditions of the matter employed in measuring instruments are such that statical equilibrium is more readily detected than dynamical moment of any stated amount.

In this particular test none of the quantities P, p, and p'

Digitized by Google

are zero in measurement, for if p' be zero the fault's resistance vanishes, and if p and p' both be zero the fault's distance vanishes, and there is no other case.

With regard to the first objection of loss of synchronism, it is well to observe that it can be entirely eliminated if the battery supplying the electromotive force E in the figure possess sufficiently low resistance. For it appears from the figure, and admits of easy proof, that the limit of the potential P when the battery resistance becomes indefinitely reduced is E (the difference of potential between the free poles), independently of the resistance of the rest of the circuit. In other words, P = E in the case we consider, whatever value be ascribed to $(\rho + x + f)$. Although this case is practically impossible, we can approximate to it with sufficient closeness to serve our purpose. For instance, suppose that we use 20 Thomson tray cells to obtain E. The resistance of these cells will be about 5 ohms in all. Suppose $\rho = x = f = 100$ ohms, then the total resistance of the circuit is 305 ohms, and in this case, an especially favourable one for revealing differences in the value of P, a variation in f of 100 per cent., namely, to zero or to 200 ohms, produces in the first case a reduction of P in the ratio of 1,000 : 992, and an increase of P in the second case in the ratio of 1,004 : 1,000. As it is practically seldom that $(\rho + x + f)$ is so low as 300 ohms, these differences in the value of P are much greater than are generally to be expected. The following correction can always, however, be applied when the greatest possible accuracy is required.

Let P_1 be the value of P when $(\rho + x + f)$ is known, and = R (advantageously an artificial resistance). Let p_1 be the corresponding value observed for p. Let r be the resistance of the battery. Then the value of P corresponding to any observed value p_2 of p, while ρ remains unaltered, is

$$P_2 = P_1 \times \frac{R\,(h\,p_1 - k p_2) + hk\,(p_2 - p_1)}{R\,\{h\,p_1 - k\,p_2 + k\,(p_2 - p_1)\}} \quad . \quad . \quad (II.)$$

where $h = R + r$, and $k = R - \rho$.

If then a low resistance battery be employed, it is only necessary to observe the potential at p during the test, and we can then observe P at leisure. The continuity of the readings is thus uninterrupted, and if taken at specified intervals at both stations may give comparative results of greater accuracy than would in the ordinary method have been effected.

It is needless to mention that the potentials p and p^1 are to "false zero," or to that potential as zero which the cable current produces when E = 0 or the battery removed from the circuit. This has already been shown in text books on the subject, and is easily proved.

We now come to the second weak point in the test. Even when p only is observed at Station A, P is also observed, although only as a constant. The formula shows that the fault's distance x is a direct function of these two potentials, and the third obtained at Station B. Practically it is a function of three deflections—galvanometric or electrometric—and these deflections are limited to some three or four hundred divisions on two-foot divided scales. The accuracy with which x can be calculated is primarily limited to these scale divisions, for although with a bright light, a good and clean mirror in the measuring instrument, and a very fine vertical wire in the path of light, deflections may occasionally be estimated to one-tenth of a division, yet some incertitude always exists in such close reading, even from the refraction of the plate glass before the instrument. Then, again, if Thomson galvanometers be used, the currents producing deflections being, strictly speaking, proportional to the tangents of half the deflection angles, correction must be introduced for this error.* Also the resistance of the fault itself is generally varying more or less throughout the test, and a corresponding change is produced in the potential deflections. These causes combine to render accurate reading uncertain and difficult, and the error which on this account alone may enter into the result is considerable. To take a simple case, suppose that the values in potential of a single division in deflection are equal for the instruments at A and B, and that

Deflection P at Station A was 301 divisions, but by reading error was noted as 300,

Deflection p at Station A was 199 divisions, but by reading error was noted as 200,

Deflection p' at Station A was 101 divisions, but by reading error was noted as 100,

Then from the accepted readings $x = \rho$;
but from the true deflections $x = \cdot957\,\rho$,
an error of more than 4 per cent.

Fig. 2, however, represents an arrangement in which part of the objection is overcome by the partial introduction of the Wheatstone bridge null method, and its greater accuracy in place of one potential deflection.

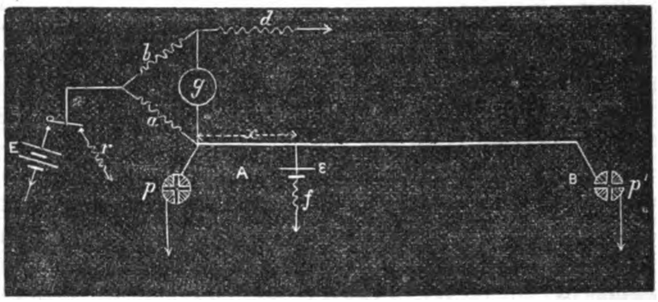

FIG. 2.

Formula (1) may be written

$$x = (x + f)\left(\frac{p - p'}{p}\right) \quad . \quad . \quad . \quad . \quad (III.)$$

where $$(x + f) = \frac{p\,\rho}{P - p} \quad . \quad . \quad . \quad . \quad . \quad (IV.)$$

Regarded in this light P serves to measure $(x + f)$.

This can be done with far more accuracy by the bridge, as shown. P is thus dispensed with, and

$$x = d\left(\frac{p - p'}{p}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (V.)$$

when $a = b$.

p and p' are measured as before.

A can now make his deflection larger than before, and in that way increase the accuracy of his reading. To take the preceding example, $d = (x + f) = 1{\cdot}95\,\rho$, which we may suppose to be measured accurately. Now, suppose A adjusted p until it became twice as great as before. Suppose his true deflection to be 398 divisions, and that he read it as 399, while B's reading was 99, read as before 100. Then the apparent distance of the fault would be $\cdot9734\,\rho$, while the true distance would be $\cdot957\,\rho$, as before. The percentage of error has thus been reduced from 4 to $1\frac{1}{2}$.

The current at A is sent on depressing a key whose back contact is earthed through a resistance, r, equal to the internal resistance of the battery.

At first sight, it might be supposed that the electromotive force resident in the fault would not act upon the potential measurers at p and p' in quite the same manner when a bridge and divided circuit are employed, as in simple circuit only, but we shall now prove that this is not the case. Let $(x + f) = y$.

Then, by applying Kirchoff's laws in the usual way, and eliminating the successive currents, we find, calling c_5 the current passing through the galvanometer g,

$$c_5 = \frac{+\{E(by - ad)\} \pm \epsilon\{r(a+b) + a(b+d)\}}{g\{(a+y)(b+d) + r(a+b+d+y)\} + r\{(a+b)d + y)\} + bd(a+y) + ay(b+d)} \quad (VI.)$$

If now $\epsilon = 0$ the second compound term in the numerator of this fraction vanishes. If E = 0 the first vanishes. The current c_5 is therefore the sum, or difference, of two perfectly independent currents, and if we adjust our galvanometer zero to the deflection produced by the electromotive

* Vide Kempe's "Handbook of Electrical Testing," page 25.

Digitized by Google

force ϵ, when the key is at rest, and we find no change in the deflection on introducing E, we know that the current whose numerator is the first term, and denominator, the whole denominator of the above fraction, is zero, so that $\frac{a}{b} = \frac{d}{y}$.

This proves that the galvanometer g can be read to false zero, which, of course, is universally admitted; we shall now in the same manner show that p and p' may be read to false zero.

Let c_4 be the current in the line or y.

Then

$$c_4 = \frac{E\{b(d+g)+d(a+g)\} \pm \epsilon\{b(d+g)+d(a+g)+ab+r(a+b+g)\}}{(r+y)\{b(d+g)+d(a+g)\}+a\{b(d+g)+g(d+r)\}+y\{ab+r(a+b+g)\}} \quad \text{(VII.)}$$

In this equation we see again that if $\epsilon = 0$ the second compound term in the numerator vanishes, and when $E = 0$ the first vanishes; so that c_4 is the sum or difference of two currents each independent of the other.

If p_m and p_n be the potentials at the extremities of any portion of y whose resistance is k, then by Ohm's law, if c_4 be the current flowing in y,

$$p_m - p_n = kc_4 \quad . \quad . \quad . \quad . \quad \text{(VIII.)}$$

Now let $E = 0$, and suppose that in consequence p_m, p_n, and c_4 become ϕ_m, ϕ_n, and c respectively,

Then $$\pm \phi_m \mp \phi_n = \pm kc. \quad . \quad . \quad . \quad . \quad \text{(IX.)}$$

Again, let $\epsilon = 0$, and suppose that in consequence p_m, p_n, and c_4 become Φ_m, Φ_n, and c respectively, then

$$\Phi_m - \Phi_n = kC \quad . \quad . \quad . \quad . \quad . \quad \text{(X.)}$$

Now let p_m, p_n, ϕ_m, ϕ_n, c_4, and c be all known, and let Φ_m and Φ_n be required. We have already seen that $c_4 = C \pm c$ from equation (VII.), and therefore

$$(p_m - p_n) = (\Phi_m - \Phi_n) \pm (\phi_m - \phi_n) \quad . \quad \text{(XI.)}$$

Therefore

$$\begin{aligned} \Phi_m - \Phi_n &= (p_m - p_n) \mp (\phi_m - \phi_n) \\ &= (p_m \mp \phi_n) - (p_n \mp \phi_n) \quad . \quad \text{(XII.)} \end{aligned}$$

From this we see that if the readings of p and p' are observed when the key at A is at rest, the potentials due to the electromotive force E are the sums or differences of these readings and those obtained when the key at A is depressed. In other words, the readings of p and p' are to "false zero."

To obtain still greater accuracy, those terminals of the potential measurers p and p', which are shown in the figure as directly connected to earth, may be respectively connected to sets of Varley slides or suitably arranged resistance through which currents of known strength flow to earth. Some point in this resistance is found at which the potential is the same as at p or p', both for the test reading and false zero. From these data the potentials can be directly deduced. Galvanometers may be employed if all the connections are well insulated and sharp contacts only made in their circuit until balance has been nearly obtained, otherwise the insulation of the points p and p' will be interfered with.

The test then becomes entirely a "null method." In practice it has yielded excellent results.

We may here remark that if the cable be long, and $(L - x)$ Fig. 1 several hundred miles, p' will have to be corrected for the loss by leakage through the dielectric. This correction is fully developed in Kempe's "Handbook," Chapter XXI., but for this bridge test the simplest formula is, perhaps,

$$\text{True } p' = (\text{Apparent } p') \frac{\left\{ e^{my}\left(\frac{Rm}{r}+1\right) + e^{-my}\left(\frac{Rm}{r}-1\right) \right\}}{\frac{2\,Rm}{r}} \quad \text{(XIII.)}$$

where $m = \sqrt{\frac{r}{i}}$

„ r = conductor resistance of unit length of cable,

„ i = dielectric resistance of unit length of cable,

„ y = approximate length in units of cable from B to the fault,

„ e = base of Naperian logarithms,

„ R = the resistance through which cable is to earth at B.

This formula applies more particularly to the case in which p' is measured by a galvanometer and high resistance. If, however, $R = \infty$, we have

$$\text{True } p' = (\text{Apparent } p') \frac{e^{my} + e^{-my}}{2} \quad . \quad . \quad \text{(XIV.)}$$

This is the formula given on page 286 of the above mentioned work.

We have hitherto considered the test as operative upon a single cable, but where a second and perfect cable is available to form a loop, there are one or two cases which it will be well to examine.

Whenever a loop test is available with a faulty cable, some modification of the Varley loop test is almost always adopted for localisation purposes. It were idle to deny the advantages which this form of the Wheatstone bridge possesses, its freedom from earth current, its sensitiveness, and its simplicity. For short cables it is doubtful if there be any other test to equal it in accuracy, but when the cables are long, and the temperature of the sea in which they are submerged comparatively high, the Varley balance cedes to the potential method in efficiency when the fault is near to the testing station. It is just in such cases that the Varley balance is most liable to error. Strict analysis shows, for one reason, that the ordinary correction for resultant fault is true only when the absolute insulation does not fall below a standard always reached in cables of great length. If the fault be near the centre of the loop the errors on each side tend to cancel each other, and to disappear, but the error on the contrary has almost its greatest effect when the fault is near the testing station. Another reason is that the metallic resistance of the loop which enters into the calculation for the fault's distance is not an exactly measurable quantity, and if it were, the correction to apply for loss by leakage is very complicated. In long cables this resistance of the loop, even though measured without the use of any earth at the testing station, is a function of the insulation of the cable, the resistance and position of the fault, and consequently it increases with the time the current has been applied. Polarisation generally interferes at the fault with the rate of increase in the observed readings, amd no tests taken while the cables are of normal insulation can entirely reproduce the conditions met with. In fact, the Varley loop test on long cables is, when fully developed, a very complicated inquiry.

Some advantage is gained, however, by not taking the resistance of the loop into account. It is only necessary to know the added resistance required to obtain balance, and the position by previous observations of the electrical centre in the loop; for when a resistance, R, has been added to one side of the faulty loop the position of the apparent fault is obviously $\frac{R}{2}$ ohms from the loop's centre on that side. This centre can be found while both cables are good by earthing the loop at the distant station, or, what is the same thing, putting both cables to earth there. A Varley balance then gives the added resistance needed to make the apparent cable-resistances equal, and after correction for leakage has been applied the loop's centre is directly found. This is always a more accurate result than any generally afforded by observed copper resistances of the cables separately, for obvious reasons. The apparent resistance of some long cables of good insulation differs from the resistances they would appear to have when the insulation would become infinite by as much as 150 ohms at the end of the first minute.

From these errors the potential test is free. The annual variation in resistance observed in long, shallow-water cables does not affect the electrical position of the fault determined by its aid. Provided the condition of the cable beyond the fault be homogeneous, or at least present some simple sequence, the effect of leakage can be very fairly eliminated, and *cœteris paribus* it is specially applicable to faults near the testing station, as the formula shows.

When a loop is available Fig. 3 represents, perhaps, the most sensitive arrangement of any that has been yet tried.

Digitized by Google

The two galvanometers are balanced to false zero by the adjustment of $a\ b\ d\ b'$ and d'. Then we have

$$(x + f) = y = \frac{a d z}{b z - a d} \quad . \ . \ . \ . \ . \quad \text{(XV.)}$$

$$x = \frac{ob'd}{bz - ad} \quad . \ . \ . \ . \ . \quad \text{(XVI.)}$$

where $z = (b' + d')$. b' is corrected for leakage in $L - x$ by (XIV). The previous reasoning, as regards the correctness of reading g and g' to false zero, applies perfectly to this arrangement. If executed with care, and the insulation of all the apparatus be insured, the test is ordinarily very accurate.

We should endeavour to make g and g' as sensitive as possible. In practice their sensitiveness will be generally limited by the strength of the earth current. If this should interfere greatly, it is well to place a little shunted low-resistance battery in the direct line circuit, that is at the end of x, and by adjustment the electromotive forces may be made to cancel each other's effects. We may then promote the sensitiveness of the arrangement by suitably adjusting the resistances $a\ b\ b'\ d$ and d'.

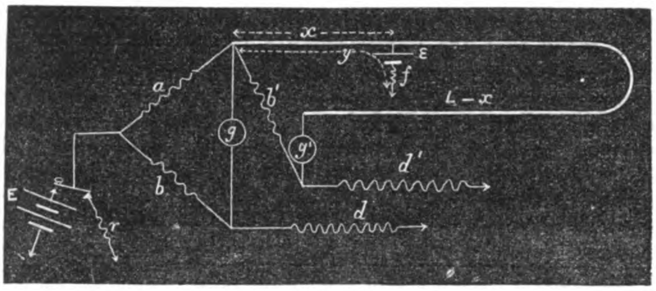

Fig. 3.

Into an examination of the best values for these resistances for any given value of y we need not enter. The subject is fully developed in "Kempe's Handbook," chapter VIII. We may, however, notice that it is specially advantageous to make $(b' + d')$ or z in the last equation as great as the sensitiveness of galvanometer g' will admit, for it is the object of the main bridge $a\ b\ g\ d$ to measure y, and if z be small not only will $\frac{y z}{y + z}$ be much less than y, but any change of resistance which may take place in y will be represented by only a small proportional change in d. In fact, if

$$\phi (y) = \frac{y z}{y + z}. \quad . \ . \ . \ . \quad \text{(XVII.)}$$

$$\phi' (y) = \frac{z^2}{(y + z)^2}. \quad . \ . \ . \quad \text{(XVIII.)}$$

and this fractional differential coefficient increases as z is increased, up to the limit unity, which we may express by saying that when $a = b$ and the currents in g and $g' = 0$, a single ohm's variation in y will produce a variation in d, increasing in amount from zero when $z = 0$ up to one ohm when z is infinite, x and f correspond to a' and x' respectively in Kempe's formulæ, and both are fixed quantities as regards the subsidiary bridge $x\ f\ b'\ d'\ g'$. To find in any case the best values for b' and d' from these formulæ we must remember that when the electromotive force at the fault may be neglected and the current in $g = 0$

$$r' = a + \frac{r (b + d)}{b + d + r}. \quad . \ . \ . \ . \quad \text{(XIX.)}$$

where r' is the resistance of the theoretical battery, and if $a = b$

$$E' = \frac{d E}{b + d + 2r} \times \frac{\lambda + r'}{\lambda}. \quad . \ . \quad \text{(XX.)}$$

where E' is the electromotive force of the theoretical battery, and λ is

$$\frac{y z}{y + z}.$$

Both these quantities are altered by altering the values of b' and d', so that the values required have to be obtained by successive approximation. Practically, Varley's slides answer well for $(b' + d')$, and with them z is always a constant quantity.

We may observe that there is an error with slides, which is readily made if care be not taken, and that is finding a slide reading at which balance is obtained with the earth current on g' while the battery key is at rest, and then taking a fresh reading to true zero when the key is depressed. It might at first sight be supposed that the difference of the two readings would measure the ratio of potentials p and p', but this is not the case, for when we balance to the earth current we merely observe the ratio of the potentials at p and at p' due to that earth current, and unless a special constant be taken there is no means of transmuting this reading to the ratios which the battery current gives. In fact, g and g' must be read strictly to false zero.

In conclusion, I have merely to observe that the forms of potential test described above have proved so useful to me, at times, too, when no other method tried yielded accurate results, that I am anxious that they may serve others equally well.—Yours, &c.,

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: As the action of the Gramme ring is a question of much interest, I trust you will allow me to occupy some of your space by some further remarks with reference to Dr. Paget Higgs's second letter on the subject in your issue of the 26th May.

First, let me point out that the conclusions I ventured to question were (a) that gaps in the iron of the ring did not affect the "magnetic screen," and the inference that Antoine Breguet's screen theory was wrong; and (b) that "the inner wires were as efficacious as the outer wires." I did not argue that the inner wires were useless, as I think Breguet showed that they are of some service, although not nearly as useful as the other wires.

In his second letter Dr. Higgs allows that my suggested experiments are in favour of the supposition that the E.M.F. is due to the cutting of the lines of force by the wires; and that the number cut, and, consequently, the E.M.F. developed, is greatest in the case of the outer wires. But he discards this explanation in favour of one which, as I understand it, makes the presence of magnetic poles in the ring the cause of the E.M.F., the action being equal on inside and outside wires. He says:—"There are clearly two actions that may occur in the Gramme ring, (1) the constant approach and retrocession of an element of the ring into and from the magnetic field, (2) the cutting of the lines of force by the wires of the ring." I must confess that I find it very difficult to separate the effects of these actions from one another. Dr. Higgs contends that of these two causes of E.M.F., the second, in practice, may be neglected; and that "the greatest E.M.F. is undoubtedly due to (1), or the determination of the lines of force into the iron of the ring considered as a circular electro-magnet." Is not this rather contradictory? Dr. Higgs first says that "the cutting of the lines of force by the wires of the ring may be neglected," and then that "the determination of the lines of force into the iron of the ring is undoubtedly the greatest cause of E.M.F."

In producing E.M.F. we may, I suppose, take it that Faraday was right in teaching that magnetism acted by means of external lines of force, and, if this is the case, it is difficult to agree with Dr. Higgs that "the E.M.F. depends on the strength of the poles induced in the ring," rather than on the cutting of the lines of force; since the only action of the pole in the ring must be that due to its lines of force.

The experiment Dr. Higgs first describes to support his view—that of shortening the pole pieces—seems to me rather inconclusive. Does not the experiment point rather to a use-

Digitized by Google

less passage of lines of force from pole to pole outside the ring? If the poles had been still longer at the commencement of the experiment the increase of E.M.F. would have been still greater; and if they had touched each other, or had been joined by a keeper, the E.M.F at starting would have been *nil*.

The second experiment of winding a ring drum fashion, and then ring fashion, rather favours my view than the reverse, as the E.M.F. was greater in the latter case than in the former. I should not have been prepared to find it "nearly twice as great," however; and as this expression is rather vague and the point is one of great interest, may I ask Dr. Higgs if he will kindly state what the increase really was?

To bear out his conclusion that the E.M.F. is the result of the poles in the ring, and is not caused by cutting the lines of force, as well as to show that inner and outer wires are equally efficacious, Dr. Higgs relates a third experiment, according to which a Schuckert ring, with poles on one side only, gave an E.M.F. only "2 to 3 per cent." below that obtained when it was moving between the usual four poles. This result was so extraordinary and so unexpected, affecting as it did the whole question of the construction of at least two well-known dynamo machines—the Schuckert and the Brush—that I repeated the experiment. My results differed very widely, however, from those of Dr. Higgs. Using the same external circuit in each case, separately exciting the field magnets, and maintaining a steady speed, I found that with four poles the product of current and E.M.F. in the external circuit was a little *more than* 100 *per cent. greater* than when two poles were employed; and this proportion was practically the same whether the field-magnets were saturated or not.—Yours, &c., W. M. Mordey.

May 30, 1883.

"DEAD TELEPHONES."—HOW DEAD TELEPHONES ARE MADE TO TALK IN THE UNITED STATES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The Chicago *Inter Ocean* of April 22 finds evidence of the discovery of the telephone in 1865, as then published in the *Diritto* of Rome, July 10, also in *Echo d'Italia* of New York, U.S., August 19, 1865. The United States patent laws forbid the granting of patents on all discoveries that have been published in this or any foreign country. In the face of these facts the Patent Office has granted over 200 telephone patents since 1876, all based upon Signor Manzetti's claim of the "*transmission of the sound of the human voice by electricity*," as published in 1865. The American *Relay Telephone* claims discovery of *the transmission of sounds* by the earth's polarity, and that the electric currents magnetise or polarise the wire so as that sounds made at one end are heard instantly at the other. In telegraphy the polar circle around the wire is invisible.

But with three thousand times larger electric currents we get the polar light as now used in Haverley's Theatre. That without any of the popular "*vibratory or undulatory movements of electricity*" passes down and encircles the wire as quiet as molasses runs off of a straw.

Herein we find the polarity circle visible that when less intensive, acts in unison with the magnetic polar nerve tension, in creating the same sound instantly at both ends, when made at one end.

That man who discovered how to transfer the disturbing sounds of the human voice from one end of the magnet in a telephone in unison with the corresponding attraction and repulsion at the other end of the magnet, so as to harmonise at the polar centre of the line (which can only be accomplished by an adjustable device on the telephone, or in connection with the line, in order to fully comply with the undeviating law of polarity), must be the first man who discovered the telephone. This discovery was made by Henry C. Strong (a printer) at Galesburg, Illinois, in 1856, who published the polarity principle of the transmission of sounds in the *Peoria Statesman* in 1858. And he matured his discovery in the city of Chicago in 1876 by the use of a metallic diaphragm over one of Professor Morse's sounders. His discovery has been confirmed by patent from the United States on "The Relay Telephone," Dec. 21st, 1880. Chicago, therefore, has a just claim on prior discovery of the telephone against the world. And as within the last twenty years our country has engaged in creating wonderful reputations and then taking them away all along the line, it now remains with the United States Court to say which end of this telephone line. See *Official Gazette*, March 27, 1883; commissioners' decision—"Drawbaugh *v* Blake"—on the Bell transmitter. Then see April number, 17th. A patent issues to Drawbaugh as the prior discoverer of this transmitter, which is virtually only one end of a telephone. A. G. Bell obtained a patent in 1876, and one in 1877, both inoperative, for running both ends of a telephone (and remains so to this day), and by his infringement of Drawbaugh's end, in the Blake transmitter, he has managed to make a fortune out of both ends of the telephone in the United States.

Quite clever for John Bull!

Polar friction may, however, cause a little tremor in telephone stocks. Hedging is now in order.—Yours, &c.,

J. Barry Strong.

Barnes House, Chicago, May 21, 1883.

ELECTRIC LIGHT INQUIRY IN EDINBURGH.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Unless the public hear the other side of the question as regards the local inquiry in Edinburgh as to the want of the electric light there, a wrong impression may be conveyed by the paragraph in your journal as well as others.

It is stated that our advocate stated in opening that "he had not the benefit of the attendance of any of the responsible members of the company to help him."

Their attendance upon a local inquiry of the nature this inquiry was intended to be was not required. It was solely to ascertain whether the light was required, and this our agents were prepared to, and did, most conclusively prove; any other matter as to our position, financial or otherwise, we are quite prepared to prove before the Board of Trade. Had we received any intimation that the members of the Board of Trade intended to go over the ground traversed on the 11th and 15th May at Whitehall we should have prepared; but, having had none, it was simply our duty to prove, what had been stated before them on those two days, that the inhabitants of our compulsory area A wished to have the light, and this was done in a most satisfactory manner.

The matter will be brought before the Board again very probably, when, perhaps, they may see their way to alter their decision.—Yours, &c.,

Fred. M. Brockelbank, Secretary,
Brush Electric Light and Power Company of Scotland (Limited).

Dashwood House, New Broad-street, E.C., June 6, 1883.

THE SHADOW OF COMING EVENTS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: As an aspiring young electrician, I have read with great interest your account of the education and success of the eminent John Pender, Esq., M.P., who made a start in life hereabouts.

During the past winter I happened to be a student in drawing at the College of Science and Arts, Glasgow, where hanging on the wall I saw a picture bearing the following inscription:—"Design by John Pender, that gained in 1835-36 the gold medal given by Gavin Walker, Esq."

Coming events cast their shadows before.—Yours, &c.,

C. G. S.

THERMOPILES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In answer to "C. D. S.," the proportions for the alloy in Clamond's thermopile are two parts antimony to one of zinc.—Yours, &c., Edgar Smart.

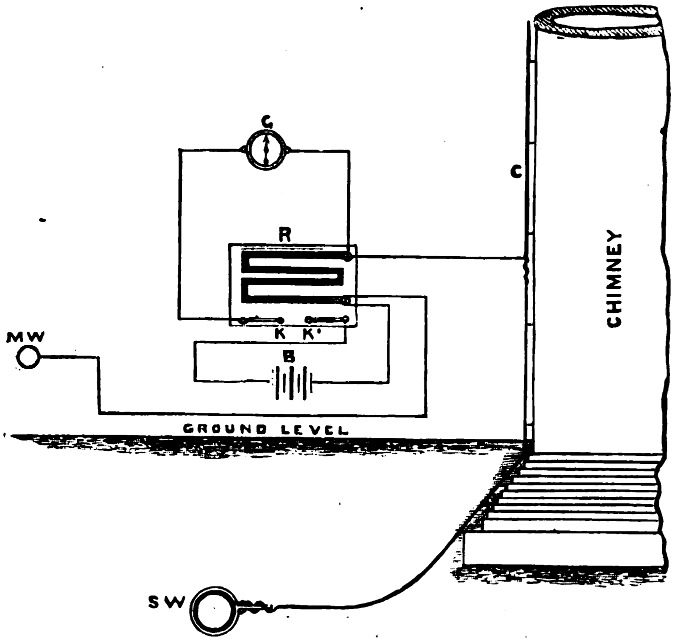
TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Replying to the letters in your issue for last week on the above subject, allow me to state in as few words as possible the conditions under which I made the tests communicated to you on the 22nd ult.

The instruments used were as follow, viz., a box of resistance coils with Wheatstone bridge, and a galvanometer having 10 ohms resistance with the current from three Leclanché cells. A No. 16 gutta percha insulated copper wire was twisted round the conductor as high up as possible, and carefully soldered thereto. This joint was made on No. 2 conductor, about 40ft. from the ground, while it was only 6ft. from the ground on No. 3. A good "earth" was got for the battery by soldering a No. 16 bare copper wire to the nearest lead water pipe, in connection with the main water system of the town. All being now ready, and the apparatus properly connected, the test for the "earth" of the conductor may be made in a few minutes without any assistance beyond that previously required to solder the wires to conductor and pipe.

The following diagram will illustrate the arrangement, and show the connections:—



G is the galvanometer, R the resistance coils and Wheatstone bridge, B the battery, C the conductor on the chimney, S W the "earth" of the conductor under test, consisting of a copper band clamped round a 15in. water pipe to the sea, with the lower end of the conductor threaded through small holes in a free end and soldered. M W the battery "earth"—a lead water pipe in connection with the main water supply.

On manipulating the keys K K' and the plugs in the box R the resistance of the conductor "earth" is easily ascertained in the manner described in the text books. The resistance is not constant; it varies considerably within certain limits. I have got in one day, at intervals of several minutes between the tests, the following results, viz., ·31, ·75, ·7, ·6, ·56, ·63, ·63, ·46, and ·56 ohm as that of "earth" resistance. This variation may also be due to polarisation of the battery, or other cause which I have not been able to determine.

I had an opportunity of testing the conductors by connecting a temporary wire to the spear, as was done at the Assembly Hall, Edinburgh, but I am inclined to think there is much less fear of bad joints in the conductor than of bad "earth." When an opportunity arises, however (which will be shortly in the case of one), I mean to have our conductors tested also. If the results turn out interesting, I may communicate them to you. Meantime, I hope some of your other correspondents will give your readers the benefit of their experience in this matter.—Yours, &c., T. L. P.

Greenock, 5th June, 1883.

P.S.—Please read *loose* for *hose* in the 16th line from the bottom of my letter of the 22nd ult.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

(CONTINUED FROM PAGE 66.)

FRICTIONAL, OR STATIC, ELECTRICITY.

HISTORY IN RELATION TO THE ELECTRIC TELEGRAPH.

Thales' call,
He, whose enquiring mind paused musingly
On the mysterious power, to action roused
By amber rubbed. This power (to him) a spirit,
Woke from its slumbers by all-wondrous art.
—Oersted's "The Soul in Nature," p. 157 of Bohn's edition.

The science of electricity is a comparatively modern creation, dating only from the commencement of the seventeenth century. It owes nothing, or almost nothing, to antiquity, and, in this respect, forms a remarkable contrast to most of the other branches of human knowledge—notably those of astronomy and mechanics, heat and light. The vast discoveries, says Lardner,† which have accumulated respecting this extraordinary agent, by which its connection with, and influence upon, the whole material universe, its relations to the phenomena of organised bodies, the part it plays in the functions of animal and vegetable vitality, its subservience to the uses of man as a mechanical power, its intimate connection with the chemical constitution of material substances —in fine, its application in almost every division of the sciences, and every department of the arts, have been severally demonstrated, are exclusively and peculiarly due to the spirit of modern research, and, in a great degree, to the labours of the present age.

Yet it is not that, in this case, nature had concealed her secrets with more than her usual coyness, for we find, scattered through the writings of the ancients, many observations on a class of phenomena, which, if rightly examined, must have led to the establishment of electricity as a department of physics.

That amber acquires, by friction, the power of attracting light bodies, such as bits of straw, wood, and dry leaves, is a fact which is probably as old as the discovery of the substance itself. Thales, one of the seven wise men of Greece, described the property six hundred years before Christ, and not as if it were with him a new phenomenon, but rather as a familiar illustration of his philosophical tenets.‡ Aristotle, Pliny, and other Greek and Roman writers, also record the fact, and even sometimes mention luminous appearances attending the friction ("Plin," Book 37, chap. 3). Theophrastus, B.C. 321, on the authority of Diocles, speaks of the *lapis lyncurius*, supposed to be our modern tourmaline, as possessing the same property as amber, adding that it attracts not only straws and leaves, but copper also, and even iron, if it be in small particles ("De Lapidibus," p. 124, Hill's edition).

The emission of sparks from the human body, when submitted to friction, had also been noticed, as in the case of Servius Tullius, the sixth King of Rome, whose locks were frequently observed to give off sparks under the operations of the toilette. Eustathius, Bishop of Thessalonica A.D. 1160, cites another instance in his "Commentarii ad Homeri Iliadem," that of a certain ancient philosopher, who, occasionally, when changing his dress, emitted sparks, and, sometimes, even entire flames, accompanied by crackling noises. He also mentions the case of Walimer, a Gothic chief, who flourished A.D. 415, who used to give off sparks from his body.§ ("In Iliad." E, p. 515, Roman ed.)

* The author reserves all rights of translation.

† "Manual of Electricity, Magnetism, and Meteorology," Vol. I., p. 2.

‡ He ascribed to amber some living principle, some soul, which could be roused to action by friction, and, in the spirit of the age, it was declared sacred. For the same reason, the loadstone was venerated, it being supposed to possess an immaterial spirit under the influence of which it attracted iron. (Aristotle, "De Anima" I., 2.)

§ We do not notice the frequent allusions in the pages of Cæsar, Livy, Plutarch, and others, to flames at the points of the soldiers' javelins, at the tops of the masts of ships, and, sometimes, even on the heads of the sailors themselves; for all these phenomena, though now known to be of the same nature as those described in the text, were then regarded simply as manifestations of the Gods. See a very interesting example of this in Plutarch's "Life of Timoleon," Vol. III., p. 16, Dacier's edition. In the early ages of the Church, the Popes were often reckoned as magicians, Gregory VII. being held in especial awe, because when he pulled off his gloves fiery sparks issued from them.

Digitized by Google

The Greeks and Romans were not the only people of antiquity to whom these phenomena were familiar. Thus, in the Persian language amber is called *Káh-rubá*, or, attractor of straw, as the magnet is called *Ahang-rubá*, or attractor of iron. In the old Persian romance, "The Loves of Majnoon and Leila," the lover says of his adored one, "She was as amber, and I but as straw; she touched me, and I shall ever cling to her." In the writings of Kuopho, a Chinese physicist of the fourth century, we read, "The attraction of a magnet for iron is like that of amber for the smallest grain of mustard seed. It is like a breath of wind, which mysteriously penetrates through both, and communicates itself with the rapidity of an arrow." Humboldt, after referring to this interesting fact, tells us how he himself had observed, with astonishment, on the woody banks of the Orinoco, in the sports of the natives, that the excitement of electricity by friction was known to these savage races. Children, he says, may be seen to rub the dry, flat, and shining seeds, or husks, of a trailing plant until they are able to attract threads of cotton and pieces of bamboo cane. ("Cosmos," London, 1849 ed., Vol. 1, p. 176.)

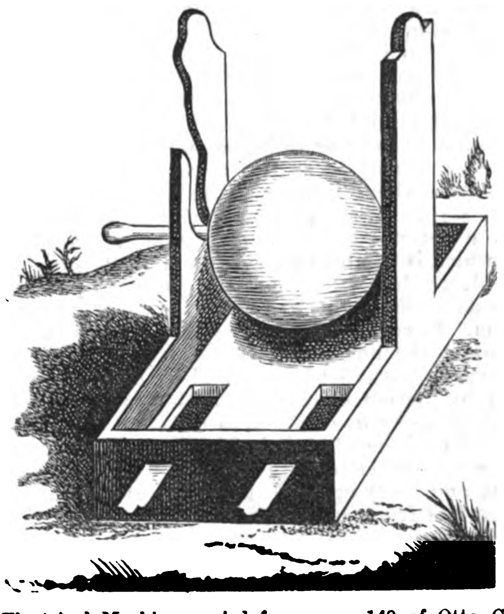
Such phenomena, says Lardner, in the work from which we lately quoted, attracted little attention, and provoked no scientific research. Vacant wonder was the most exalted sentiment they raised; and they accordingly remained, while centuries rolled away, barren and isolated facts upon the surface of human knowledge. The vein whence these precious fragments were detached, and which, as we have shown, *cropped out* sufficiently often to challenge the notice of the miner, continued unexplored; and its splendid treasures were thus reserved to reward the toil, and crown the enterprise, of modern times. (Vol. I., p. 4.)

Without going the length of asserting that electrical phenomena were entirely neglected during the long night of the middle ages, it seems certain that, with the exception of the discovery of the electrical property of jet, little advance was made up to the close of the sixteenth century. Then it was that Dr. Gilbert, of Colchester, for the first time collected the scattered fragments, and, with many valuable observations of his own, shaped them into the nucleus of a new science, to which he gave the name Electricity, from the Greek word ἤλεκτρον, signifying amber. In his great work, "De Magnete,"* published in the year 1600, he described the only three substances known up to his time as susceptible of electrical excitation, and added a variety of others, such as spars, jems, fossils, glasses, and resins, which enjoyed, equally with them, the power of attracting not only light bodies, like feathers and straws, but all solid and fluid matter, as metals, stones, water, and oil. He also observed some of the circumstances which affect the production of electricity, such as the hygrometric state of the atmosphere. Thus, he noticed that when the wind blew from the north and east, and was dry, the body could be excited by a brisk and light friction continued for a few minutes, but that when the wind was from the south and moist it was difficult, and sometimes impossible, to excite it at all. In order to test the condition of the various substances experimented upon, Gilbert made use of a light needle of any metal, balanced, and turning freely on a pivot, like the magnetic needle, to the extremities of which he presented the bodies after excitation. Some of Gilbert's deductions were curiously fallacious. In pointing out, for instance, the distinction between magnetic and electric attraction, he affirmed that magnets and iron mutually attracted each other, but that when an electric was excited it alone attracted, the substances attracted remaining inactive. He noticed also, as a special distinction between magnetism and electricity, that the former repelled as well as attracted, whilst the latter only attracted ("De Magnete," Lib. II., cap. II.—IV.).

The few references to electricity in the works of Sir Francis Bacon, Nicholas Cabeus, Kenelm Digby, Gassendi, Descartes, Thomas Browne, and others, may be passed over in silence, as they are chiefly theoretical, and did not contribute in any way to the advancement of the science.†

The celebrated Robert Boyle, to whom some of the other physical sciences owe such great obligations, directed much of his attention to the subject of electricity, and has left us an account of his experiments, in a small work, entitled "Experiments and Notes about the Mechanical Origine or Production of Electricity, London, 1675." By means of a suspended needle, he discovered that amber retained its attractive virtue after the friction which excited it had ceased; and though smoothness of surface had been regarded as advantageous for excitation, yet he found a diamond, which, in its rough state, exceeded all the polished ones, and all the electrics which he had tried, it having been able to move the needle three minutes after he had ceased to rub it. He found also that heat and "tersion" (*i.e.*, the cleaning or wiping of any body) increased the electrical effect; and that if the attracted body were fixed, and the attracting one movable, their approach would take place all the same, thus disproving one of Gilbert's deductions. To Dr. Gilbert's list of electrics, he added several new ones, as glass of antimony, white sapphire, white amethyst, carnelian, &c. Like all his predecessors, Boyle, in whom, by the way, the theorising faculty was particularly strong, speculated, in his turn, on the causes of electrical phenomena; but it seems that he, as well as they, could find no better explanation than that offered by the Ionic sage, twenty-three centuries before. The supposition was that the excited body threw out a glutinous, or unctuous, effluvium, which laid hold of small bodies in its path, and, on returning to its source, carried them along with it.* The *Philosophical Transactions* of this period contain some learned disquisitions in support of this (now strange) hypothesis, and even experiments are described which were considered as conclusive of its correctness (*Phil. Trans.* for 1699, Vol. 21, p. 5.)

Otto Guericke, burgomaster of Magdeburg, and inventor of the air pump, was contemporary with Boyle, and to him we owe some most important advances. In 1671, he constructed the first electrical machine, by means of which he was able to produce electricity in far greater quantities than had hitherto been possible from the friction of glass or sulphur rods. With this machine, which consisted of a globe of sulphur,† mounted on a revolving axis, and excited by the friction of a cloth held in the hand, he discovered the "hissing noise and gleaming light" which accompany strong electrification.



The First Electrical Machine, copied from page 148 of Otto Guericke's "Experimenta Nova," &c., by kind permission of Mr. Latimer Clark.

To him also belongs the discovery of the property of electrical repulsion. He ascertained that a feather, when attracted to an excited electric, was instantly repelled, and was incapable of a second attraction, until it had been touched by the finger or some other body. He also observed that a feather, when thus repelled, always kept the same side towards the excited electric—

* This book, although mainly devoted to magnetism, has many pages on Electricity; and, besides its intrinsic value, is interesting as containing the first publications on our subject. William Gilbert was a member of the College of Physicians, London, and became Physician in Ordinary to Queen Elizabeth, who, conceiving a high opinion of his learning, allowed him an annual pension to enable him to prosecute his studies. He died in 1603.

† Jacob Böhmen, the Teutonic theosopher, who lived 1575 to 1624, and who wrote largely on astrology, philosophy, chemistry, and divinity, has some pages devoted to electricity. See *Notes and Queries*, July 28, 1855, page 63.

* Boyle is sometimes said to have been the first, in modern times, to observe the electric light—an assertion which seems to be based upon his observation, in 1663, of the light which some diamonds gave out, in the dark, after being rubbed. But it is doubtful if this was not an optical, rather than an electrical effect, an instance of what may be called latent light, and, therefore, belonging to the class of phenomena, of which the celebrated Bologna stone, discovered in 1602 by the quondam shoemaker Casiorolus, was the first recorded example, as Balmain's luminous paint is the last. For much interesting information on this subject, see Sir D. Brewster's "Letters on Natural Magic."

† Sulphur, it may be remarked, was a favourite electric with early experimenters, as it was imagined that electricity was emitted with the sulphurous effluvium produced by the friction. In the construction of his machine, Guericke, for example, cast the sulphur in a glass globe, which he afterwards broke, so as to expose the sulphur to the action of the rubber, little imagining that the glass globe itself would have answered his purpose just as well.

Digitized by Google

a fact the correspondence of which with the position of the moon towards the earth, induced him and other philosophers to assume that the revolution of the moon round the earth might be explained on electrical principles. Again, in the observation that a substance becomes electric by being merely brought near to another electrified body, Guericke discovered the fact, though not the principle, of induction ("Experimenta Nova Magdeburgica," Amstelodami, 1672, Lib. IV., cap. 15).

Newton, about the same time, published another effect of induction, viz.: one side of a glass plate being electrified, the other side will also be electrified, and will attract any light bodies within its influence. Laying upon a table a disc of glass two inches broad, in a brass hoop or ring, so that it might be one-eighth of an inch from the table, and then rubbing it briskly, little pieces of paper, laid upon the table under the glass, moved nimbly to and fro, and twirled about in the air, continuing these motions for a considerable time after he had ceased rubbing. Upon sliding his finger over the glass, though he did not agitate it nor, by consequence, the air beneath, he observed that the papers, as they hung under the glass, would receive some new motion, inclining this way or that, according to the direction of his finger. The Royal Society had ordered this experiment to be repeated at their meeting of December 16, 1675, and, in order to ensure its success, had obtained a full account of it from its distinguished author. The experiment, however, failed, and the secretary requested the loan of Sir Isaac's apparatus, inquiring, at the same time, whether or not he had guarded against the papers being disturbed by the air which might have somewhere stolen in? In replying, on the 21st of December, Newton advised them to rub the glass "with stuff whose threads may rake its surface, and if that will not do, rub it with the finger ends to and fro, and knock them as often upon the glass." Following these directions the society succeeded, on January 13, 1676, when they used a scrubbing brush of short hog's bristles, and the heft of a knife made with whalebone! (See Brewster's "Life of Sir Isaac Newton,;' pp. 307-8; or Birch's "History of the Royal Society," Vol. III., pp. 260-70).

In the 8th and 27th queries at the end of his treatise on "Optics," Newton has introduced the subject of electricity in such a manner as to convey some notion of the theoretical views which he had been led to form. He says (8th query):—"A globe of glass about 8 or 10 inches in diameter being put into a frame where it may be swiftly turned round, its axis will, in turning, shine where it rubs against the palm of one's hand applied to it; and if at the same time a piece of white paper be held at the distance of half an inch from the glass, the electric vapour, which is excited by the friction of the glass against the hand, will, by dashing against the paper, be put into such an agitation as to emit light, and make the paper appear livid, like a glowworm. In rushing out of the glass, it will even sometimes push against the finger so as to be felt." And again, in the 27th query, he says:—"Let him also tell me how an electric body can, by friction, emit an exhalation so rare and subtile, and yet so potent, as by its emission to cause no sensible diminution of the weight of the electric body, and to be expanded through a sphere whose diameter is above two feet, and yet to be able to agitate and carry up leaf copper, or leaf gold, at the distance of above a foot from the electric body."*

(TO BE CONTINUED.)

THE CAUSE OF EVIDENT MAGNETISM IN IRON, STEEL, AND OTHER MAGNETIC METALS.†

(CONCLUDED FROM PAGE 63.)

Neutrality.

The apparatus needed for researches upon evident external polarity requires no very great skill or thought, but simply an apparatus to measure correctly the force of the evident repulsion or attraction; in the case of neutrality, however, the external polarity disappears, and we consequently require special apparatus, together with the utmost care and reflection in its use.

From numerous researches previously made by means of the induction balance, the results of which I have already published, I felt convinced that, in investigating the cause of magnetism and neutrality, I should have in it the aid of the most powerful instrument of research ever brought to bear upon the molecular construction of iron, as indeed of all metals. It neglects all forces which do not produce a change in the molecular structure, and enables us to penetrate at once to the interior of a magnet or piece of iron, observing only its peculiar structure and the change which takes place during magnetisation or apparent neutrality.

The induction balance is affected by three distinct arrangements of molecular structure in iron and steel, by means of which we have apparent external neutrality.

Fig. 1. shows several polar directions of the molecules as indicated by the arrows. Poisson assumed, as a necessity of his theory, that a molecule is spherical, but Dr. Joule's experimental proof of the elongation of iron by $\frac{1}{720000}$ of its length when magnetised, proves at least that its form is not spherical; and, as I am unable at present to demonstrate my own views as to its exact form, I have simply indicated its polar direction by arrows, the dotted oval lines merely indicating its limits of free elastic rotation.

In Fig. 1, at A, we have neutrality by the mutual attraction of each pair of molecules, being the shortest path in which they could satisfy their mutual attractions. At B we have the case of superposed magnetism of equal external value, rendering the wire or rod apparently neutral, although a lower series of molecules are rotated in the opposite direction to the upper series, giving to the rod opposite and equal polarities. At C we have

Fig. 1.

the molecules arranged in a circular chain around the axis of a wire or rod through which an electric current has passed. At D we have the evident polarity induced by the earth's directive influence when a soft iron rod is held in the magnetic meridian. At E we have a longitudinal neutrality produced in the same rod when placed magnetic west, the polarity in the latter case being transversal.

In all these cases we have a perfectly symmetrical arrangement, and I have not yet found a single case in well-annealed soft iron in which I could detect a heterogeneous arrangement, as supposed by Ampère, De la Rive, Weber, Wiedermann, and Maxwell.

We can only study neutrality with perfectly soft Swedish iron. Hard iron and steel retain previous magnetisations, and an apparent external neutrality would, in most cases, be the superposition of one magnetism upon another of equal external force in the opposite direction, as shown at B, Fig. 1. Perfectly soft iron we can easily free, by vibrations, from the slightest trace of previous magnetism, and study the neutrality produced under varying conditions.

If we take a flat bar of soft iron, of 30 or more centimetres in length, and hold it vertically (giving, while thus held, a few torsions, vibrations, or, better still, a few slight blows with a wooden mallet, in order to allow its molecules to rotate with perfect freedom), we find its lower end to be of strong north polarity and its upper end south. On reversing the rod and repeating the vibrations we find that its lower end has precisely a similar north polarity. Thus the iron is homogeneous, and its polarity symmetrical. If we now magnetise this rod to produce a strong south pole at its lower portion, we can gradually reverse this polarity, by the influence of earth's magnetism, by slightly tapping the upper extremity with a small wooden mallet. If we observe this rod by means of a direction needle at all parts, and successively during its gradual passage from one polarity to the other, there will be no sudden break into a haphazard arrange-

* These appear to be the only published observations of the great Sir Isaac on electrical matters, but it would seem that, in moments of leisure from weightier business, he bestowed an occasional glance on the infant science. This will be apparent from the following extract from an autograph letter, which Mr. Latimer Clark has lately unearthed, and which will be found in full in *The Electrician* Journal for April 16, 1881:—"I have been much amused by ye singular φενομενα resulting from bringing of a needle into contact with a piece of amber or resin fricated on silke clothe. Ye flame putteth me in mind of sheet lightning on a small (how very small) scale." Although this letter is dated "London, December 15, 1716," it would seem from the wording that Newton was unaware of similar comparisons instituted, several years before, by Hauksbee and Wall.

† Paper read before the Society of Telegraph Engineers and of Electricians by Prof. D. E. Hughes, F.R.S., Vice-President, May 24, 1883.

ment, but a gradual and perfectly symmetrical rotation from one direction to that of the opposite polarity.

If this rod is placed east and west, having first, say, a north polarity to the right, we can gradually discharge or rotate the molecules to zero, and as gradually reverse the polarity by simply inclining the rod so as to be slightly influenced by earth's magnetism; and at no portion of this passage from one polarity to neutrality, and to that of the opposite name, will there be found a break of continuity of rotation or haphazard arrangement. If we rotate this rod slowly, horizontally or vertically, taking observations at each few degrees of rotation of an entire revolution, we find still the same gradual symmetrical change of polarity, and that its symmetry is as complete at neutrality as in evident polarity.

In all these cases there is no complete neutrality, the longitudinal polarity simply becoming transversal when the rod is east and west. F, G, H, I, J, Fig. 1, show this gradual change, H being neutral longitudinally, but polarised transversely. If, in place of the rod, we take a small square soft iron plate and allow its molecules freedom under the sole influence of the earth's magnetism, then we invariably find the polarity in the direction of the magnetic dip, no matter in what position it be held, and a sphere of soft iron could only be polarised in a similar direction. Thus we can never obtain complete external neutrality whilst the molecules have freedom and do not form an internal closed circle of mutual attractions; and whatever theory we may adopt as to the cause of polarity in the molecule, such as Coulomb's, Poisson's, Ampère's, or Weber's, there can exist no haphazard arrangement in perfectly soft iron as long as it is free from all external causes except the influence of the earth; consequently these theories are wrong in one of their most essential parts.

We can, however, produce a closed circle of mutual attraction in iron and steel, producing complete neutrality as long as the structure is not destroyed by some stronger external directing influence.

Oersted discovered that an external magnetic needle places itself perpendicular to an electric current, and we should expect that, if the molecules of an iron wire possessed inherent polarity and could rotate, a similar effect would take place in the interior of the wire to that observed by Oersted. Wiedermann first remarked this effect, and it has been known as circular magnetism. This circle, however, consists really in each molecule having placed itself perpendicular to the current, simply obeying Oersted's law, and thus forming a complete circle, in which the mutual attractions of the molecules forming that circle are satisfied, as shown at C, Fig. 1. This wire becomes completely neutral, any previous symmetrical arrangement of polarity rotating to form its complete circle of attractions; and we can thus form in hard iron and steel a neutrality extremely difficult to break up or destroy. We have evident proof that this neutrality consists of a closed chain, or circle, as by torsion we can partially deflect them on either side, thus from a perfect externally neutral wire, producing either polarity, by simple mechanical angular displacement of the molecules, as by right or left-handed torsion.

If we magnetise a wire placed east and west, it will retain this polarity until freed by vibrations, as already remarked. If we pass an electric current through this magnetised wire, we can notice the gradual rotation of the molecules, and the formation of the circular neutrality. If we commence with a weak current, gradually increasing its strength, we can rotate them as slowly as may be desired. There is no sudden break or haphazard moment of neutrality; the movements to perfect zero are accomplished with perfect symmetry throughout.

We can produce a more perfect and shorter circle of attractions by the superposition of magnetism, as at B, Fig. 1. If we magnetise a piece of steel or iron in a given direction with a strong magnetic directing power, the magnetism penetrates to a certain depth. If we slightly diminish the magnetising power, and magnetise the rod in a contrary direction, we may reduce it to zero, by the superposition of an exterior magnetism upon one of a contrary name existing at a greater depth; and if we continue this operation, gradually diminishing the force at each reversal, we can easily superpose ten or more distinct symmetrical arrangements, and, as their mutual attractions are satisfied in a shorter circle than in that produced by electricity, it is extremely difficult to destroy this formation when once produced.

The induction balance affords also some reasons for believing that the molecules not only form a closed circle of attractions, as at B, but that they can mutually react upon each other, so as to close a circle of attractions as a double molecule, as shown at A. The experimental evidence, however, is not sufficient to dwell on this point, as the neutrality obtained by superposition is somewhat similar in its external effects.

We can produce a perfectly symmetrical closed circle of attractions of the nature of the neutrality of C (Fig. 1), by forming a steel wire into a closed circle, 10 centimetres in diameter, if this wire is well joined at its extremities by twisting and soldering. We can then magnetise this ring by slowly revolving it at the extremity of one pole of a strong permanent magnet; and, to avoid consequent poles at the part last touching the magnet, we should have a graduating wedge of wood, so that whilst revolving it may be gradually removed to greater distance. This wire will then contain no consequent points or external magnetism; it will be found perfectly neutral in all parts of its closed circle. Its neutrality is similar to C (Fig. 1); for if we cut this wire at any point we find extremely strong magnetic polarity, being magnetised by this method to saturation, and having retained (which it will indefinitely) its circle of attractions complete.

I have already shown that soft iron, when its molecules are allowed perfect freedom by vibration, invariably takes the polarity of the external directing influence, such as that of the earth, and it does so even with greater freedom under the influence of heat. Manufacturers of electro-magnets for telegraphic instruments are very careful to choose the softest iron and thoroughly anneal it; but very few recognise the importance as regards the position of the iron whilst annealing it under the earth's directing influence. The fact, however, has long since been observed.

Dr. Hooke, 1684, remarked that steel or iron was magnetised when heated to redness and placed in the magnetic meridian. I have slightly varied this experiment by heating to redness three similar steel bars, two of which had been previously magnetised to saturation, and placed separately with contrary polarity as regards each other, the third being neutral. Upon cooling, these three bars were found to have identical and similar polarity. Thus the molecules of this most rigid material, cast steel, had become free at red heat, and rotated under the earth's magnetic influence, giving exactly the same force on each; consequently the previous magnetisation of two of these bars had neither augmented nor weakened the inherent polarity of their molecules. Soft iron gave under these conditions by far the greatest force, its inherent polarity being greater than that of steel.

I have made numerous other experiments bearing upon the question of neutrality, but they all confirm those I have cited, which I consider afford ample evidence of the symmetrical arrangement of neutrality.

Superposed Magnetism.

Knowing that by torsion we can rotate or diminish magnetism, I was anxious to obtain by its means a complete rotation from north polarity to neutrality, and from neutrality to south polarity, or to completely reverse magnetic polarity by a slight right or left torsion.

I have succeeded in doing this, and in obtaining strong reversal of polarities, by superposing one polarity given whilst the rod is under a right elastic torsion, with another of the opposite polarity given under a left elastic torsion, the neutral point then being reached when the rod is free from torsion. The rod should be very strongly magnetised under its first or right-hand torsion, so that its interior molecules are rotated, or, in other words, magnetised to saturation; the second magnetisation in the contrary sense and torsion should be feebler, so as only to magnetise the surface, or not more than one-half its depth. These can be easily adjusted to each other so as to form a complete polar balance of force, producing when the rod is free from torsion, the neutrality as shown at B, Fig 1.

The apparatus needed is simply a good compound horse-shoe permanent magnet, 15 centimetres long, having six or more plates, giving it a total thickness of at least 3 centimetres. We need a sufficiently powerful magnet, as I find that I obtain a more equal distribution of magnetism upon a rod or strip of iron by drawing it lengthwise over a single pole in a direction from that pole, as shown in Fig. 2; we can then obtain saturation by repeated drawings, keeping the same molecular symmetry in each experiment.

In order to apply a slight electric torsion when magnetising rods or wires, I have found it convenient to attach two brass clamp keys to the extremities of the rods, or simply turn the ends at right angles, as shown in the following diagram, by which means we can apply an elastic twist or torsion whilst drawing the rod over the pole of the permanent magnet. We can thus superpose several and opposite symmetrical structures, producing a polar north or south, as desired, greatly in excess of that possible under a single or even double magnetisation, and by carefully adjusting the proportion of opposing magnetisms, so that both polarities have the same external force, the rod will be at perfect external neutrality when free from torsion.

If we now hold one end of this rod at a few centimetres distance from a magnetic directive needle, we find it perfectly neutral when free of torsion, but the slightest torsion right or left at once produces violent repulsion or attraction, according to the direction of the torsion given to the rod, the iron rod or strips of

Digitized by Google

hoop iron which I use for this experiment being able, when at the distance of five centimetres from the needle, to turn it instantly 90deg. on either side of its zero.

The external neutrality that we can now produce at will is absolute, as it crosses the line of two contrary polarities, being similar to the zero of my electric sonometer, whose zero is obtained by the crossing of two opposing electric forces.

This rod of iron retains its peculiar powers of reversal in a remarkable degree, a condition quite different to that of ordinary magnetisation, for the same rod, when magnetised to saturation under a single ordinary magnetism, loses its evident magnetism by a few elastic torsions, as I have already shown; but when it is magnetised under the double torsion with its superposed magnetism, it is but slightly reduced by variations or numerous torsions, and I have found it impossible to render this rod again free from its double polar effects, except by strongly re-magnetising it to saturation with a single polarity. The superposed magnetism then becomes a single directive force, and we can then by a few vibrations or torsions reduce the rod to its ordinary condition.

The effects of superposed magnetism and its double polarity I have produced in a variety of ways, such as by the electro-magnetic influence of coils, or in very soft iron simply by the directive influence of the earth's magnetism, reversing the rod and torsions when held in the magnetic meridian, these rods when placed magnetic west showing distinctly the double polar effects.

It is remarkable, also, that we are enabled to superpose and obtain the maximum effects on thin strips of iron from ¼ to ½ millimetre in thickness, whilst in thicker rods we have far less effect, being masked by the comparatively neutral state of the interior, the exterior molecules then reacting upon those of the interior, allowing them to complete in the interior their circle of attractions.

I was anxious to obtain wires which would preserve this structure against the destructive influence of torsion and vibrations, so that I could constantly employ the same wires without

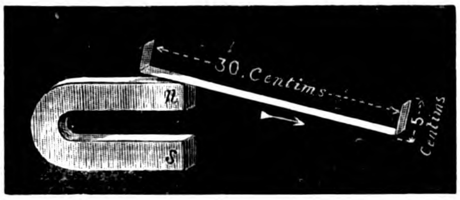

Fig. 2.

the comparatively long and tedious process of preparation. Soft iron soon loses the structure, or becomes enfeebled, under the constant to and fro torsions requisite where we desire a constant change of polarity, as described later in the magnetic bells. Hard steel preserves its structure, but its molecular rigidity is so great that we obtain but mere traces of any change of polarity by torsion. I have found, however, that fine cast drill steel, untempered, of the kind employed by watchmakers, is most suitable; these are generally sold in straight lengths of 30 centimetres. Wires 1 millimetre in diameter should be used, and when it is desired to increase the force, several of these wires, say nine or ten, should be formed into a single rod or bunch.

The wire as sold is too rigid to give its maximum of molecular rotation effect. We must therefore give it two entire turns or twists to the right, and strongly magnetise it on the north pole of the magnet whilst under torsion. We must again repeat this operation in the contrary direction, after restoring the wire to its previous position, giving now two entire turns to the left and magnetising it on the south pole. On restoring the wire to its original place, it will be extremely flexible, and we may now superpose several contrary polarites under contrary torsions, as already described.

The power of these wires, if properly prepared, is most remarkable, being able to reverse their polarity under torsion, as if they were completely saturated; and they preserve this power indefinitely if not touched by a magnet. It would be extremely difficult to explain the action of the rotative effects obtained in these wires under any other theory than that which I have advanced; and the absolute external neutrality that we obtain in them when the polarities are changing, we know, from their structure, to be perfectly symmetrical.

I was anxious to show, upon the reading of this paper, some mechanical movement produced by molecular rotation, consequently I have arranged two bells that are struck alternately by a polarised armature put in motion by the double polarised rod I have already described, but whose position, at three centimetres distant from the axis of the armature, remains invariably the same. The magnetic armature consists of a horizontal light steel bar suspended by its central axle; the bells are thin wine glasses, giving a clear musical tone loud enough, by the force with which they are struck, to be clearly heard at some distance. The armature does not strike these alternately by a pendulous movement, as we may easily strike only one continuously, the friction and inertia of the armature causing its movements to be perfectly dead-beat when not driven by some external force, and it is kept in its zero position by a strong directive magnet placed beneath its axle.

The mechanical power obtained is extremely evident, and is sufficient to put the sluggish armature in rapid motion, striking the bells six times per second, and with a power sufficient to produce tones loud enough to be clearly heard in all parts of the hall of the society. As this is the first direct transformation of molecular motion into mechanical movement, I am happy to show it on this occasion.

There is nothing remarkable in the bells themselves, as they evidently could be rung if the armature was surrounded by a coil, and worked by an electric current from a few cells. The marvel, however, is in the small steel superposed magnetic wire producing by slight elastic torsions from a single wire, 1mm. in diameter, sufficient force from mere molecular rotation to entirely replace the coil and electric current.

Elastic Nature of the Ether Surrounding the Magnetic Molecules.

During these researches I have remarked a peculiar property of magnetism, viz., that not only can the molecules be rotated through any degree of arc to its maximum, or saturation, but that, whilst it requires a comparatively strong force to overcome its rigidity or resistance to rotation, it has a small field of its own through which it can move with excessive freedom trembling, vibrating, or rotating through a small degree with infinitely less force than would be required to rotate it permanently on either side. This property is so marked and general that we can observe it without any special iron or apparatus.

Let us take a flat rod of ordinary hoop-iron, 30 or more centimetres in length. If, whilst holding this vertically, we give freedom to its molecules by torsions, vibrations, or, better still, by a few blows with a wooden mallet upon its upper extremity, we find, as is well known, that its lower portion is strongly north, and its upper south. If we reverse this rod, we now find it neutral at both extremities. We might here suppose that the earth's directing force had rotated the molecules to zero or transversely, which in reality it has done, but only to the limit of their comparatively free motion; for, if we reverse the rod to its original position, its previous strong polarity reappears at both extremities, thus the central point of its free motion is inclined to the rod, giving by its free motion great symmetrical inclination and polarity in one direction, but when reversed the inclination is reduced to zero.

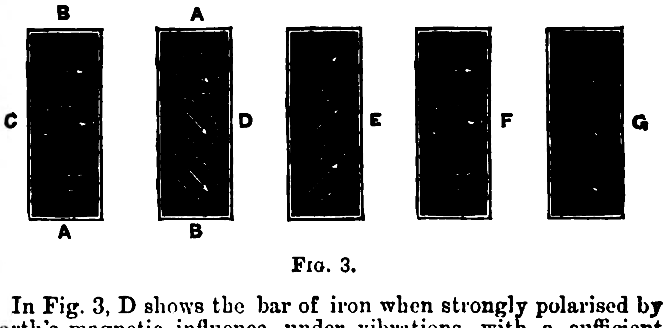

Fig. 3.

In Fig. 3, D shows the bar of iron when strongly polarised by earth's magnetic influence, under vibrations, with a sufficient force to have rotated its elastic centre of action. C shows the same bar with its molecules at zero, or transversal, the directing force of earth being insufficient without the aid of mechanical vibration to allow them to change. The dotted lines of D suppose the molecule to be in the centre of its free motion, whilst at C the molecules have rotated to zero, as they are prevented from further rotation by being at the extreme end of its free motion.

If, now, we hold the rod vertically, as at C, giving neutrality, and give a few slight blows with a wooden mallet to its upper extremity, we can give just the amount of freedom required for it to produce evident polarity, and we then have equal polarity, no matter which end of the bar is below, the centre of its free rotation here being perfect, and the rod perfectly neutral longitudinally when held east and west. If, on the other hand, we have given too much freedom by repeated blows of the mallet, its centre of free motion becomes inclined with the molecules, and we arrive at its first condition, except that it is now neutral at

Digitized by Google

D, and polarised at C. From this it will be seen that we can adjust the centre of action, by vibrations or blows, to any point within the external directing influence.

We can perceive this effect of free rotation in a limited space in all classes of iron and steel, being far greater in soft Swedish iron than in hard iron or steel. A similar phenomenon takes place if we magnetise a rod held vertically in the direction of earth's magnetism. It then gives greater polarity than if magnetised east or west, and if magnetised in a contrary sense to earth's magnetism, it is very feebly magnetised, or, if the rod is perfectly soft, it becomes neutral after strong magnetisation. This property of comparative freedom, and the rotation of its centre of action, can be demonstrated in a variety of ways. One remarkable example of it consists in the telephone. All those who are thoroughly acquainted with electro-magnetism, and know that it requires measurable time to charge an electro-magnet to saturation (about $\frac{1}{15}$ of a second for those employed in telegraphy), were surprised that the telephone could follow the slightest change of timbre, requiring almost innumerable changes of force per second. I believe the free rotation I have spoken of through a limited range explains its remarkable sensitiveness and rapidity of action, and, according to this view, it would also explain why loud sounding telephones can never repeat all the delicacy of timbre that is easily done with those only requiring a force comprised in the critical limits of its free rotation. This property, I have found, has a distinct critical value for each class of iron, and I propose soon to publish researches upon the molecular construction of steel and iron, in which I have made use of this very property as a guide to the quality of the iron itself.

The elastic rotation (in a limited space) of a molecule differs entirely from that known as mechanical elasticity. In perfectly soft iron we have feeble *mechanical* elasticity, whilst in tempered steel we have that elasticity at its maximum. The contrary takes place as regards *molecular* elasticity. In tempered steel the molecules are extremely rigid, and in soft iron its molecular elasticity is at its maximum. Its free motion differs entirely from that given it by torsion or stress. We may assume that a molecule is surrounded by continuous ether, more of the nature of a jelly than of that of a gas; in such a medium a molecule might freely vibrate through small arcs, but a rotation extending beyond its critical limit would involve a much greater expenditure of force.

The discovery of this comparatively free rotation of molecules, by means of which, as I have shown, we can (without in any degree disturbing the external mechanical elasticity of the mass) change the axes of their free motion in any direction desired, has led me into a series of researches which have only indirectly any relation with the theory of magnetism. I was extremely desirous, however, of finding an experimental evidence which in itself should demonstrate all portions of the theory, and the following experiment, I believe, answers this purpose:—

Let us take a square soft iron rod, 5 millimetres in diameter by 30 or more centimetres in length, and force the molecules, by aid of blows from a wooden mallet, as previously described, to have their centres of free motion in one direction, the rod will (as already shown) have polarity at both ends, when held vertically; but, if reversed, both ends become completely neutral.

If now we turn the rod to its first position, in which it shows strong polarity, and magnetise it whilst held vertically, by drawing the north pole of a sufficiently powerful permanent magnet from its upper to its lower extremity, we find that this rod, instead of having south polarity at its lower portion, as we should expect from the direction of the magnetisation, is completely neutral at both extremities, but if we reverse the rod, its fullest free powers of magnetisation now appear in the position where it was previously neutral. Thus, by magnetisation, we have completely rotated its free path of action, and find that we can rotate this path as desired in any direction by the application of a sufficient directing power.

If we take a rod as described, with its polarities evident when held vertically, and its neutrality also evident when its ends are reversed in the same magnetic field, we find that its polarity is equal at both ends, and that it is in every way symmetrical with a perfect magnet. If we *gradually* reverse the ends and take observations of its condition through each degree of arc passed over, we find an equal symmetrical diminution of evident external polarity until we arrive at neutrality, when it has no external trace of inherent polarity, but its inherent polarity at once becomes evident by a simple return to its former position. Thus the rod has passed through all the changes from polarity to neutrality, and from neutrality to polarity, and these changes have taken place with complete symmetry.

The limits of this paper do not allow me to speak of the numerous theoretical evidences as shown by the use of my induction balance. I believe, however, that I have cited already experimental evidences to show that what has been attributed to coercive force is really due to molecular freedom or rigidity; that in inherent molecular polarity we have a fact admitted by Coulomb, Poisson, Ampère, De la Rive, Weber, Du Moncel, Wiedermann, and Maxwell; and that we have also experimental evidence of molecular rotation and of the symmetrical character of polarity and neutrality.

The experiments which I have brought forward in this paper, in addition to those mentioned in my paper read before the Royal Society, will, I hope, justify me in having advanced a theory of magnetism which I believe in every portion allows at least experimental evidences of its probable truth.

ON INCANDESCENT LIGHTING.*

BY WILLIAM SIEMENS.

The words incandescent light have no thoroughly precise meaning, and there are lighting arrangements passing under this name which have nothing whatever to do with the subject of my paper. I shall only treat of those incandescent lights which actually consist of a glowing carbon filament at a white heat in a vacuum.

Carbon is a conductor of the electric current, and is heated by the passage of the same. This heating of the carbon can reach a certain white glow by strengthening the current without injury to it. When this degree of heating is reached and remains constant, a continuous flowing of the current in the unit of time is necessary, to which then a fixed radiation in the same period corresponds. The power, which is expended by the current on the carbon, is represented as $E\,C = \frac{E^2}{R} = C^2\,R$, where E represents the difference of potential measured at the two ends of the carbon filament, C the actual strength of the current, and R the resistance of the carbon. The corresponding light given out by this power with a fixed heating is proportional to the extent of the surface of the carbon. Let l be the length of the carbon and d its circumference (in which case the section is taken as a circle), then the surface $= l\,d$. For the equilibrium between current = work and radiation the relation stands thus (leaving out the constants and assuming identical heating and identical materials), $E\,C = l\,d$.

It is clear that under the limitations above mentioned the product $l\,d$ also furnishes a measure for that part of the total radiation which presents itself in the form of lighting heat rays or light, in contradistinction to the dark and chemical heat rays.

Thus to a fixed quantity of light or to a fixed total of light rays corresponds a definite extent of the surface of the carbon and a definite work performed by the current. The performance of this work remains unaltered, though both the factors of the product E C be varied in such a way that the product itself remains constant. The larger E the smaller will C be. Thus for the same performance of work correspond currents of the most varied character, small currents of high E.M.F. and large currents of low E.M.F. Therefore, the resistance R also varies consistently with the $= \frac{E^2}{R} = C^2\,R =$ constant.

From $E\,C = l\,d =$ constant it follows $\frac{E}{l} = \frac{d}{C}$, from which it is to be seen that corresponding to the variation of E and C also the factors l and d of the constant product $l\,d$ vary.

One is therefore in a position for the production of light of a given strength, which (assuming identical temperature and identical materials) corresponds to a definite surface, to use carbons of the most diverse shapes. Incandescent lights are thus distinguished according to the form of their carbon filaments. The lamps with long, thin filaments would require correspondingly high E.M.F., whilst the short, thick filaments require a larger current and lower E.M.F.

As a type of the high tension lamps I may mention the Edison lamp, as a type of lamps requiring greater current the Swan lamp. A characteristic difference, however, lies in the difference of the sectional area, decreasing with increasing E.M.F. A great advantage is certainly connected with the larger diameter (supposing the other conditions to be constant), to wit a greater solidity of the carbon and a longer duration.

The durability of the carbon is exposed to a series of more or less injurious influences, which in the majority of cases prove the more detrimental the smaller the filament. In this respect the purely mechanical effects of the blows and shakings to which the lamps are subjected, particularly in transit, are by no means to be underrated.

According to the mechanical gas theory the last little remains

* Translated from the *Electrotechnische Zeitschrift*, March, 1883.

Digitized by Google

of air, which even after the application of the best air pumps remain in the lamp globe in consequence of the great heating of the carbon, are found to be in very quick movement, and the filament is therefore exposed in a certain measure to a constant bombardment, to which it will offer the longer resistance the larger its sectional area.

An observation of Edison's comes in here. It is to the effect that one side of the carbon filament, though an equally directed current goes through it, is more quickly consumed than the other. In order to account for this one must imagine a kind of electrolytic process to take place. The space in the globe, therefore, is not to be considered as an absolute vacuum, but as containing air in a very highly alternated condition. In the event of this being really the case, further support is given to the contention that a thick filament lasts longer than a thin one. In addition, it is generally accepted that the electric current exercises an influence on the molecular structure of the carbon. It is observed, for instance, that copper wires which have been used for a longer time in an alternating current machine assume a different character, molecularly, from that which they possessed previous to such use.

The greater heating to which the carbon filament is exposed, so much the worse for its durability, and the above-named injurious influences are the more perceptible and make themselves especially felt in the case of the thin carbon filaments. In general a thick carbon filament will bear a greater heating than a thin one—which is of importance, not only on economical grounds, but also on æsthetical, as a greater whiteness of the light corresponds to a higher temperature.

To this advantage possessed by the lamps requiring greater current (which as I will show later on applies in a certain sense also to lamps requiring high E.M.F.) there are, however, on the other hand, greater disadvantages, and these particularly lie in costliness of the "leads." The greater C in C E the greater is the quantity of copper required.

On account of security against danger from fire, the "leads" must be so chosen that their heating through the current used in the installation does not exceed a certain measure. Respecting the proportion between strength of current and strength of wire assuming constant heating, there are three views entertained, viz: $C = d$, $C = d^2$, $C = \sqrt{d^3}$ ($d =$ diameter of the wire). The constants are, of course, here left out. In practice the second view is preferably adopted, although neither the calculations nor the results of any experiments instituted respecting this proportion agree. The question is here of bare stretched wire, and the assumption is made that no loss of heat takes place through conduction. The case is otherwise if the wire is coiled. For two coils of equal size and weight, which are covered with wire of different thickness, according to Forbes the equation is: $C = d^2$. Let C and C' stand for the strength of the current, and R and R' the resistances of the coils. Then the quantities of heat produced are $= C^2 R$ and $C'^2 R'$. As the surfaces of the two coils are equal, and the heating should be the same, the radiations must also be equal. Therefore, $C^2 R = C'^2 R'$, or $\frac{C^2}{C'^2} = \frac{R'}{R} = \frac{d^4}{d'^4}$, or $\frac{C}{C'} = \frac{d^2}{d'^2}$.

Some writers give the relation $C = \sqrt{d^3}$ as theoretically correct. It is, however, at the same time remarked that the result of experiments (as for instance those of Zollner and Forbes) does not agree with this formula, but rather with $C = d$. The equation $C = \sqrt{d^3}$ is obtained in the following manner:—$E\,C = l\,d$; $C^2 R = l\,d$; $\frac{C^2 R_s}{d^2} = d$; $C^2 R_s = d^3$. If the specific resistance $R_s = 1$, then $C = \sqrt{d^3}$.

This equation is throughout correctly deduced, but more might be considered to be in it than does lie in it, if one were to deduce therefrom that C according to the relation $C = \sqrt{d^3}$ changes with d. For, in fact, in doing so, the actual condition contained in the problem would not be taken into account, that the heating or temperature of the wire should not change by the variation of C, which amounts to this, that the radiation corresponding to a fixed extent of surface (to the unit of area for example) remains constant; or $l_1\,d_1 =$ const.; if l_1 and d_1 indicate the dimensions of this part of the surface.

This condition cannot, however, be made to accord with $C = \sqrt{d^3}$, as here no length l occurs, which is the reason why the same is not applicable here.

As already mentioned, the relation $C = d$ is confirmed by experiments. Its correctness can thus be made apparent.

$$C\,E = K\,l\,d,$$
$$C = K_1\,d,$$
$$E = K_2\,l;$$

the multiplication of these last two equations gives the first. $K\,K_1$ and K_2 are constants.

In case the conductor has any other, for instance a rectangular section, the relation generally runs: $u = C$, u representing the circumference. The quantity of copper measure in the conductor depends on the sectional area. In order to save copper, we may arrange that the sectional area for a given surface is the smallest possible. A rectangular section is therefore better than a circular one, and it is more advantageous for the "lead" to consist of several parallel thin wires than of one thick one.

The relation $d = C$ shows how comparatively unfavourable lamps requiring greater current are, as double current necessitates four times the quantity of wire.

To the result $C = d$ or $C = u$ we are brought by another consideration. In an incandescent lamp installation the conductors will consume a certain portion of the strength of the current. The resistance of the conductors should therefore be as small as possible, so that the loss in power should be a minimum. Practice allows the conductors about 10 per cent. of the power used in working the lamps, and as a consequence the resistance of the conductors amounts to 10 per cent. of the resistance of the lamps.

For lamps having the same illuminating power, temperature, and materials, the resistances are in inverse ratio to the squares of the corresponding strengths of current (follows from $C_2\,R_s =$ constant.) Thus, according to the selection of lamps requiring double or threefold strength of current, the corresponding resistance of the conductor amounts to the fourth or ninth.

(TO BE CONTINUED.)

NOTES.

Electric Lighting in Australia.—It is stated that steps are being taken to form an electric lighting company at Geelong.

Devon and Cornwall Electric Light Company.—Mr. Justice Chitty has appointed Mr. Edwards official liquidator of this company.

New Company.—The Commercial Underground Electric Company has been incorporated at New York. It is to construct, use, or lease telegraph wires.

Siam.—A Reuter's telegram dated Berne, June 12, states that the Siamese Government has notified its adhesion to the International Telegraph Convention.

Dividend.—The Eastern Extension Telegraph Company have declared an interim dividend on the old shares of 2s. 6d. per share, as well as 2s. 6d. per share on the new shares.

Royal Society.—On Thursday Mr. W. De La Rue, F.R.S., and Mr. H. Muller, F.R.S., were to read a paper before this society on "Experimental Researches with the Chloride of Silver Battery."

A Change.—Sir Charles William Siemens, F.R.S., has publicly given notice of his intention to drop his baptismal name of Charles, and desires to be known henceforth as Sir William Siemens.

Electric Light in India.—The electric light is to be introduced on the Madras Railway, and the necessary apparatus and materials are on their way from England, at least so says a contemporary.

Electric Lighting in Spain.—The Bilbao Town Council have ordered some arc and incandescent lamps from the Sociedad Espanola de Electricidad, with the object of making a trial of the electric light.

Business Notice.—The Western Electric Company, who are large manufacturers in America of telegraphic and telephonic instruments, electric bells, and other apparatus, have opened a London branch at 59, Moorgate-street.

The Duplex Electric Light Company.—A petition for the winding up of this company was presented on the 6th inst. by the British Trading Company. It is to be heard before Vice-Chancellor Sir James Bacon on the 23rd inst.

Mr. Spottiswoode.—We regret to say that the President of the Royal Society has the last few days been suffering from a severe attack of fever caught during a recent visit to Rome. The latest bulletins represent Mr. Spottiswoode as somewhat better.

A New Journal.—It is announced that a new journal, devoted to electricity, will make its appearance towards the end of this month. The title of this latest addition to the ranks of electrical journalism will be *Révue Générale d'Electricité.*

The Maxim-Weston Electric Company.—We understand the letters of allotment of the new issue of shares were posted on the 12th inst. This company has secured the lighting of the entire buildings of the Welsh Eisteddfod National Gathering.

Electric Lighting for the Suez Canal.—An Exchange Company's telegram from Paris states that M. de Lesseps has resolved to light the Suez Canal throughout its course by means of the electric light, in order to allow of the traffic through the canal being carried on day and night.

Messages for Mauritius.—The Eastern Telegraph Company (Limited) notify that a steamer leaves Durban for Mauritius and Madagascar on the 22nd instant. Messages for the above ports, intended for that opportunity, should be handed in not later than noon on the 21st instant.

The Incandescent System in France.—It is stated that a company has been started by some Englishmen in Lyons under the title of the Lyons Electrical Company. The objects are to supply electric lights on the incandescent system in and about that town. Swan lamps will be used.

The Telegraph in the Orange Free State.—The President, in his address on opening the Volksraad, expressed his hopes of a speedy conclusion of telegraphic and postal conventions, and recommended the construction by Government of a line from Colesberg to Bloemfontein, *viâ* Phillipolis, and thence *viâ* Harrismith to the Natal frontier.

Powder Magazine fired by Lightning.—A telegram from Scutari, Albania, dated June 8, says:—"The powder magazine of the fortress of Scutari was struck to-day by lightning. A great explosion followed, and a portion of the bazaar was destroyed. Many persons are reported killed." Later information says that ten soldiers and seven civilians were killed, and forty soldiers and fifteen civilians injured.

Telegraph Instruments Wanted.—The Highland Railway Company want tenders for the supply of telegraph instruments and fittings for one year, from the 1st July next. Forms of tender may be obtained on application to Mr. J. G. Bulmer, storekeeper, Inverness. Tenders, properly endorsed, sealed and addressed to the directors, must be lodged with the secretary, Mr. A. Dougall, not later than the 23rd inst.

Electric Lighting in the Provinces.—In the House of Commons on Thursday, June 7, Mr. John Holms moved for leave to introduce Bills to confirm provisional orders of the Board of Trade, under the Electric Lighting Act 1882, relating to Aston, Dudley, West Bromwich, Wolverhampton, Balsall Heath, Birmingham, Redditch, and Walsall. Leave was given; the Bills were read a first time, and referred to the examiners.

The Fisheries Exhibition.—Although only temporarily erected, we are informed that the buildings of this exhibition have been insured in the Phœnix Fire Insurance Company's Office, at an exceptionally low rate, owing to the careful manner in which the wires for the electric lights that are to be used for lighting purposes have been put up. The work of wiring was superintended on behalf of the Phœnix Company by Mr. Musgrave Heaphy, C.E.

Electric Lighting for St. Pancras.—The St. Pancras Vestry have published a notice to the effect that the Board of Trade have issued a provisional order giving them leave to supply electricity for public and private purposes within that parish, and that the Board intend to include this order in a confirmation Bill about to be introduced to Parliament. Copies of this order are to be had at the Vestry Hall, Pancras-road, N.W., at a cost of one shilling each.

The Flexion of Polarised Electrodes.—M. Gouy, in a recent note to the Academy of Sciences, describes a phenomenon which he has observed, viz., the flexion experienced by electrodes in the course of polarisation when they are formed of a thin metal plate, protected on one of its faces by a very thin layer of an insulating varnish. This peculiarity he has studied by two slightly different methods, with gold, and a saturated solution of sulphate of copper containing a little sulphuric acid.

Transmission of Power.—*L'Electricité* says:—"Another prize of 6,000 francs has been offered by the Compagnie des Mines et Cuivres de Mansfeld for the best system of transmitting power underground. The power transmitted must

Digitized by Google

not be less than 10 horses, the distance being 1 kilometre. The motor is to be placed either underground or at the surface; in the latter case, the speed of the transmission shafting and pulleys must not be more than 100 revolutions per minute. Finally, the cost of erection must not exceed that which would be incurred by the use of a steam engine."

Magnetic Lines of Force.—The method of ascertaining the distribution of the lines of force by placing paper over a magnet and sprinkling iron filings on the paper is probably known to all our readers. It may be useful, and perhaps new to some of them, however, to learn how to fix the iron filings in the positions they take up with regard to the magnet. Substitute paraffined paper for ordinary paper, and when the filings are in position pass a piece of heated metal over them so as to melt the paraffin, and then withdraw it. The paraffin will cool and the filings be permanently held in position.

Vienna Electrical Exhibition.—In addition to the Danish Naval Department, we are informed that the War Department of that kingdom will exhibit in the field telegraphy section of this exhibition. Several Danish exhibitors have lately sent in applications for space, one of whom, Francis Lund, chief of the Department for Sea Mines and Torpedoes at the Arsenal in Copenhagen, has been appointed by the Danish Government as official representative of the Danish exhibitors. He is staying at present in Vienna in order to consult and arrange with the managing committee all details respecting the Danish Exhibition, which, according to his estimate, will occupy an area of 190 square metres.

British Guiana.—At the last meeting of the Court of Policy, says the *Colonies and India*, a letter was read from the West India and Panama Telegraph Company, thanking the Government for the favourable consideration shown to its interests, and protesting against the continuance of the subsidy being made dependent upon the through working of all connecting lines, it being urged that the company can exercise no control over those lines which do not belong to them, and pointing out that arrangements were in contemplation to lay new cables from Cuba to Demerara, which, if carried out, would materially improve the present means of communication. An order for the balance outstanding due to the company, 5,979 dollars, was passed by the Court of Policy.

Electric Lighting in Cardiff.—Mr. J. B. Braithwaite, jun., chairman of the Great Western Electric Light Company, writes as follows with reference to the note in last week's issue under this head:—"The Brush lamps there referred to were not used for lighting St. Mary-street, but were, I believe, supplied privately by Mr. Carr, of the Western Mail, to some of his friends. My company has a lighting station in Cardiff, and I am happy to say that, so far from the 'Brush' light being superseded, we are constantly adding fresh lights to our station. During last month we fixed eleven fresh arc lamps, and are now busy fitting up several additional ones, as well as incandescent lamps, run in groups on the arc circuit. I may mention that we have two 25 nominal horse-power Robey engines, both of which we expect to have fully employed this autumn."

The Resistance of Mercury.—The following is an abstract of an article by R. Lenz, in Wiedemann's *Bieblätter*, Vol. VI., p. 802, which appears in this month's *Journal* of the Society of Telegraph Engineers:—"A thermometer tube, 1·2 m. long, was widened out at either end into two cups, and was filled with perfectly pure mercury which had been thoroughly dried and free from air. The current was conducted to the cups by means of platinum hooks. The tube was placed in a piezometer, in which a pressure of 60 atmospheres could be attained, and which was surrounded with ice. Two platinum wires connected the platinum hooks with the binding screws of the piezometer. The resistances were measured by the Wheatstone bridge method, with a sine galvanometer of Kohlrausch, and an electro-dynamometer. The resistance of the copper wires could be neglected, that of the platinum wires varied from 0·48 ohm to 0·256 ohm, according to the diameter. The resistance of the mercury column was about 7·11 ohms. On increasing the pressure from 0 to 60 atmospheres, the resistance decreased by 0·02 per cent. per atmosphere. The decrease is very nearly proportional to the pressure. If the tube is filled by means of Weinhold's distillation apparatus in vacuum, the resistance in the first place is 0·12 per cent. smaller than if it is filled by sucking in the mercury."

Electric Lighting for Lighthouses.—According to an American paper, President Henry Morton of the U.S. Lighthouse Board, is reported to have stated that plans for testing the lighting of lighthouses by electricity are nearly completed, and the test will be made at the entrance to the lower harbour, New York, probably at one of the two Highland lights. He believed that arc lights would not be found to be servicable for coast and harbour illumination, mainly because they waver in intensity. The lights in American lighthouses are so arranged as to throw regularly intermittent flashes to the navigator, and if the electric light should die down it would show a series of irregular flashes, and that might be very confusing. Professor Morton has been carrying on a series of experiments with incandescent lights, with a view to reach the greatest possible light. He has succeeded in obtaining 400 candle-power. An incandescent light has thus been obtained powerful enough to conduct the experiment with. Two items of considerable expense remain. The great lenses used for the lamps now in the lighthouses, it is found, serve to dissipate instead of to concentrate the rays of an electric light, so that lenses must be ground especially for the electric light. Two dynamo machines also must be at the foot of the lighthouse, one to be kept in reserve if the other should fail.

Death of Sir J. R. Carmichael.—We regret to have to announce the death of Sir James Robert Carmichael, which took place in his town house, Sussex-place, Regent's Park, on Thursday morning, the 7th June, at the age of 66. He was born on the 11th June, 1817, and was the eldest son of the late Major-General Sir James Carmichael-Smyth, C.B., of Nutwood, Surrey, by marriage with Harriet, only child of the late General Robert Morse, R.E. He was educated at Charterhouse and at the Royal Military College, Sandhurst, and was formerly an officer in the Army. He succeeded his father as second baronet in 1838. Sir James resumed his family name of Carmichael only, by Royal license, in 1841. He was a claimant to the Scottish earldom of Hyndford. The first baronet received his title in 1821, for military services, having served under Sir David Baird, Lord Lynedoch, the Duke of Wellington, &c. He commanded the Royal Engineers in the Low Countries and Waterloo, and was some time governor of British Guiana. His father, James Carmichael-Smyth, M.D., physician to George III., assumed the additional surname of Smyth, and received the thanks of Parliament for his public services. Sir J. R. Carmichael married, in 1841, Louisa Charlotte, daughter of the late Sir Thomas Butler. He is succeeded in the baronetcy by his only son, James Morse, who was born in 1844. There is also a daughter living. The deceased baronet was well known in the electrical world, as

Digitized by Google

chairman of the Submarine Telegraph Company and the Mediterranean Extension Telegraph Company, as well as a vice-president of the Electric Sun Lamp Company.

A New Insulating Compound.—Mr. C. W. Torr, of the firm of R. W. Winfield and Co., Birmingham, has recently taken out a patent for a new insulating compound. The inventor thus describes this new material in his patent:—"The essential constituents of the compositions constituting my invention are pitch, rosin, and Calais sand. These I mix in the proportions of about one part by weight of pitch, one part by weight of rosin, and two parts by weight of sand. The mixture of these materials is heated until the pitch and rosin are melted, and the semi-liquid mass is stirred until the melted pitch and rosin are thoroughly incorporated and the sand thoroughly mixed therewith. The composition is hard and somewhat brittle, and where it is likely to be exposed to concussion, or where it is desired it should be flexible, I give to it a slight flexibility by the addition of a small quantity of tallow, which is added to the other materials during the process of incorporation by heat. A composition containing one hundred parts by weight of pitch, one hundred parts by weight of rosin, two hundred parts by weight of sand, and sixteen parts by weight of Russian tallow, possesses sufficient flexibility for most purposes, and is not liable to fracture. As the addition of tallow causes the composition to soften and melt at lower temperatures than when the said composition contains no tallow, I reduce the quantity of or altogether omit the tallow where the composition is likely to be exposed to heat. By omitting the tallow and increasing the proportion of sand the composition may be made much harder, and not liable to soften at any temperature to which insulating compositions are ordinarily exposed." The number of the patent is 5129 for 1882.

Electric Discharges in Vacuum.—Herr J. Puluj, in a paper upon the streams of electrode matter, describes an apparatus by which he shows that electric discharges in vacuum can be hindered by the existence of static charges upon the walls of the vacuum space. The instrument consists of a tube of the form of a rectangle, into one of the sides of which are inserted two wire electrodes, about 8cm. from each other. Under a pressure of ·06mm. of quicksilver, electric discharges take place in the short side, in which are the electrodes, and also in the other sides of the rectangle. But if the tube in the neighbourhood of the electrodes is held between two fingers, the stream in that part of the tube is interrupted, and is strengthened in the other portions, though it may have to traverse a path perhaps five times longer than the shortest distance between the electrodes. The stopping of the discharge in highly rarefied spaces is often quoted as a proof of the untenability of the single fluid view of electricity. If, it is said, the electric current consists in the movement of an imponderable matter, the discharges ought to go on in the best vacuum, because the ether is always present. Against this view, it may be remarked that the discharges in a vacuum of constant value take place the more easily the further removed the walls of the space are from the cathode, and thus there is reason to suppose that discharges might take place even in the highest possible vacuum if it were not for the unavoidable existence of static charges upon the surface of the glass chamber. The origin of these charges may be looked for partly in the induction from the cathode, and partly in the direct transfer of static electricity by means of the particles of cathode precipitated against the glass.—*Wiedemann's Annalen.*

The Electrical Resistance of Glass.—In a note in our issue of the 26th May we gave the results of some experiments made by M. Foussereau to test the influence of tempering on the electrical resistance of glass. M. Foussereau gave some account of this method of experimenting at a recent meeting of the French Physical Society. He made use of test tubes, closed by a stopper. The current from a battery of from three to 100 volta elements was caused to traverse the thickness of these tubes, and was collected in a condenser of known capacity. The time required to communicate a known difference of potential to the armatures of the condenser was measured, the difference of potential being observed by means of a Lipmann electrometer connected to the two armatures. The most scrupulous precautions were observed to avoid all superficial conductivity. The experiments were enabled to be carried out for certain glasses as far as − 17 degrees. Bohemian glass was found to have from 5 to 20 times the conductivity of ordinary glass. Crystal, on the contrary, had 1,000 to 1,500 times more insulating power than the latter. Tempering exercised a very considerable influence on the resistance of certain glass. The author studied this influence by causing specimens of tempered glass and crystal to undergo a greater or less amount of baking. Their resistances at the same temperatures increased with the action of baking, until they became in certain cases 11 times greater. This increase in resistance became more and more marked according as the baking was hotter and more complete. It continued for some time after baking, the glass not resuming its definite molecular equilibrium directly. On the other hand, glass, whether tempered or not, which had not been heated for some time, preserved an invariable resistance. In these different experiments specimens of non-tempered glass afforded the terms of comparison.

Electrical Storms.—Speaking of the cyclonic storm which passed over the centre of the United States on the 22nd of last month, the *New York Herald* says:—"As the central area of the cyclone approached the Virginia coast, on Monday evening, a series of electric storms, or one grand electric storm, illumined the Atlantic seaboard from Virginia to New York, and violent thunderstorms were reported in Washington, Philadelphia, and New York. This brilliant and extended display was due apparently to the movement of a cool and dry stratum over the saturated surface winds, blowing from the south and east on the north-eastern margin of the cyclone, and the consequent changes of wind and temperature. The advance of the general depression with which these thunderstorms were associated was also indicated on Sunday evening at Philadelphia by the slow-moving cirrus and other clouds, while the central depression was several hundred miles distant in the south-west. But the most interesting and important phenomenon of the cyclone was that it signalled its own north-eastwardly advance by vivid electric flashes far beyond its centre. The meteorological significance of silent sheet lightning has recently been considerably discussed by scientists, with the generally accepted conclusion of experts that it is by no means a harmless display, but the signal of a coming storm, yet too remote for its thunder to be heard. This conclusion was strikingly confirmed on Monday night by the far-reaching electrical phenomena of the Virginia cyclone—a fact which forcibly suggests that the approach of many of our large cyclones, and even of the great tropical hurricanes, may be foreseen and foretold by their lightnings before instrumental indications justify a forewarning. The fiery portents of the great Cuba hurricane of September 5, 1882, were visible at Havana and Pensacola over twelve hours before the storm rose to its maximum force at these points or the barometer gave unmistakable warning.

Digitized by Google

While our thunderstorms may be local (the lightning being electrical discharges from two adjacent clouds), the phenomenon is often extended over a whole section of the country, with most serious consequences. They deserve, therefore, much more careful investigation than they have yet received. It would be a great aid to the popular understanding of the movements of thunderstorms and their relation to the large cyclones if the former were as regularly charted as the latter."

Experiments with Dynamo Machines.—M. J. Pollard has recently published the results of experiments made by himself, with the aid of Engineer Garnier and Lieutenant Journet, on board one of the ships of the French Navy. They experimented with machines of the Gramme type, having the inductors in the circuit, and their theory led them at the outset to the establishment of the following fundamental principle:—The resisting-couple developed during the working of a dynamo-electric machine is merely a function of the current which circulates in the coils, and, in consequence, the current generated is constant and independent of the behaviour or resistance of the external circuit, when the motor couple is itself constant. The numerical determination of the laws regulating the connection between current flowing in the inducing and induced coils and the electromotive force per revolution, $\frac{E}{n}$, on the one hand, and the value of the motor couple, C, on the other, necessitated the use of measuring apparatus, which they were without. They were consequently obliged to treat the question indirectly by experimentally considering the case in which a steam motor was possessed of a constant static couple, whatever were the demands made on it. Under these conditions the constancy of the current was verified in external circuits of various resistances, for which the speed of the machine was varied within wide limits. The following table gives the results of one of the experiments, in which the external circuit was composed of a hand lamp; the distance between the carbons was lengthened progressively from 0 to 6 millimetres (a millimetre is equal to about 1-25th inch), whilst the speed of the machine rose from 500 to 700 revolutions without the intensity of current indicated by the deflections of a small galvanometer varying in any marked degree. The Gramme machine was driven direct by a Brotherhood engine supplied with steam by powerful boilers, which maintained a constant pressure. As the introduction of steam into the cylinders was regulated at a fixed quantity, it might be taken for granted that the average power exerted on the pistons, and, consequently, the motor couple, was constant during the experiment:—

The Abbé Laborde.—In a recent issue of *Cosmos Les Mondes*, M. l'Abbé Moigno writes in the following terms of the death of his *confrère* and friend, L'Abbé Laborde, who died at Nevers on the 18th of May, at the age of seventy-five:—"The Abbé Laborde was, above all things, a physicist, and an experimental physicist of great ability, making his own apparatus when needful and when his resources did not place them within his reach. In the vast domain of physics, which comprises mechanics, heat, light, as well as photography, electricity, &c., he made a large number of inventions and original discoveries of very great importance. I will only enumerate a few. Let me revert to the momentous time when the need of measuring directly the incalculable velocity of light made itself felt, when great geniuses, Arago, Foucault, and Fizeau, simultaneously strove to solve the difficult problem; and its solution hovered, so to speak, in the air ready to reveal itself at several points, at the same time. It was to M. l'Abbé Laborde, however, that it first revealed itself, and here is what I can, what I ought to add in my *Repertoire d'Optique Moderne*, Vol. III., p. 1,162, to the account of that very celebrated experiment of M. Fizeau's. 'A modest man, M. l'Abbé Laborde, professor of physics at the small school of Corbigny, conceived and discussed, some five or six years ago, the experiment so admirably carried out by M. Fizeau. On this subject he wrote, five or six years before, to M. Francois Arago, a letter, lost, alas! in the huge portfolio of the observatory (like to the sea into which all the rivers are emptied and yet it never overflows); brought to light again when it was too late, and which I am glad to publish, because it gives my friend the undoubted right of priority, and a glorious title. It would be impossible for me to analyse even rapidly the innumerable communications to my dear *Cosmos* which my friend made, all sparkling with new and pregnant ideas. I will at least recall to mind the learned explanation which he was the first to give of this mysterious passage in the Book of Psalms: *Fecit fulgura in aquas;* he changed the lightning into water, and made water with the electricity of the atmosphere.' M. l'Abbé Laborde was the first to discover, and prove by direct experiment, that the electric current in penetrating to the depths of a mass of water vapour causes therein a lowering of temperature and condenses it into water. Up to his time it was only known that discharges of electricity in the atmosphere were very often followed by a heavy fall of rain. The news of the death of my eminent *confrère* has caused me great sorrow; it has left a great blank in my life, as well as a certain remorse at not having made sufficient effort to obtain for him that justice which was his due. L'Abbé Laborde should have been made a chevalier of the Legion of Honour twenty years ago. A pious priest, even more edifying than learned, he will receive in heaven, if he has not already received it, the only recompense worthy of him."

Winding Electro-magnets.—Professors W. E. Ayrton and John Perry have recently made some interesting experiments on the winding of electro-magnets, with a view to determine which mode of winding a given length of wire on an iron bar gave the strongest electro-magnet for the same current. Four bars of iron, each 12in. long, were cut from the same rod ⅜in. thick, and an exactly equal length of wire was wound on the four bars respectively, in the following way:—1. Wire wound equally over the whole length. 2. Wire coned towards each end. 3. Wire wound equally over half the iron bar, leaving the other end bare. 4. Wire wound on one half but coned towards the end. Electro-magnet No. 1 was put so that its axis was at right angles to the axis of a small magnetic needle and passed through the point of suspension of the needle, which was suspended so as to move freely in a horizontal plane, and far enough away that the magnetic field due to the electro-magnet No. 1, when magnetised by passing a current through it, was nearly constant over that portion of the field in which the little suspended needle moved when deflected. A constant current was now passed through the coil on No. 1, and the deflection of the little needle observed when No. 1 was placed at different distances from the centre of the test-needle, the axis of

Digitized by Google

No. 1, however, always remaining in the same line. Under these circumstances it is well known that the strength of the field produced by No. 1 at the centre of the test-needle is approximately proportional to the tangent of its deflection. Experiments were now made in a similar way with electro-magnet No. 2, and with each end of No. 3 and of No. 4, the same current as was employed with electro-magnet No. 1 being used in all cases, and which was much below the saturating current. It was found that the effect of coning the wire was to produce a strong field very near the pole, but that the force fell off very rapidly as the distance from the pole increased. The uniformly coiled magnet No. 1 was found to produce the most powerful field at considerable distances from the end of the electro-magnet, while for points nearer the magnet, but still at a distance of about 3in. from it, the covered end of No. 3 magnet produced the strongest field, the next strongest being produced by magnet No. 2 with the wire coned towards each end. To ascertain the force which each magnet would exert on an armature, experiments were made, and the following results obtained, the current flowing through the coil in each case being exactly the same, as well as the armature employed:—

Magnet.	Weight required to detach the armature from the covered end of the magnet.
No. 1	45 ounces
„ 2	57 „
„ 3	57 „
„ 4	77 „

These results confirmed the previously-ascertained fact that the field produced by the covered ends of the electro-magnets numbers 2 or 3 at distances near the pole was much stronger than that produced by No. 1. They also showed that for very small distances the covered end of No. 4 produced the strongest field. From these experiments Messrs. Ayrton and Perry conclude that with a definite iron core, a definite length of wire to be coiled on it, and to be traversed by a definite current, the mode of coiling to produce the largest field depends entirely on the distance from the end of the electro-magnet at which the field is to be produced. With the particular magnet employed by them it is seen that, at distances from the end of the magnet very small compared with the length of the core, the wire should be coiled up at the near end of the core; to create a field at a distance from the end of the magnet equal to about a third of the length of the magnet, it is better to coil the wire uniformly over one-half of the core than to cone it up at the near end; while for distances from the end of the magnet, equal to, or greater than, about $\frac{1}{3}$ of the length of the core, the uniform mode of winding is the best. The experimenters thank two of their students, Messrs. Sayers and Pink, for their cordial assistance in the above experiments, a more detailed account of which, with illustrations, will be found in the *Philosophical Magazine* for June.

Electrolytic Experiments.—In further continuation of our recent note under this head, we take the following from the *Journal* of the Chemical Society for May, describing some experiments made by A. Bartoli and G. Papasogli, on the electrolysis of solutions of hydrofluoric acid and of potassium antimonate, with carbon electrodes, the original description of which appeared in the *Gazzetta*, Vol. 13, pp. 22—27:—(1). *Electrolysis of Hydrofluoric Acid:* When wood-charcoal or gas-retort carbon, after purification by chlorine, is used as the positive electrode in the electrolysis of aqueous hydrofluoric acid, it is partly disaggregated, swelling up in the immersed part, and becoming so brittle that after a while it splits up by its own weight into rather large fragments, whereas the carbon at the negative electrode remains quite unaltered. On repeatedly washing the altered carbon till the wash-water is no longer acid, then drying it at 100deg., reducing it to impalpable powder, repeatedly boiling it with hydrochloric acid, and once more thoroughly washing it with water, it exhibits the following properties:—1. It dissolves partially, with dark-red colour, in strong sulphuric acid. 2. It is attacked by a hot solution of sodium hypochlorite, yielding sodium fluoride, mellic acid, and the usual derivatives of the latter. 3. In addition to carbon, hydrogen, and oxygen, it contains fluorine, amounting to about 3 per cent. of the disaggregated carbon, and not due to electrolysis of mineral matter, inasmuch as the carbon used in the experiment did not yield on ignition any perceptible quantity of ash. When graphite is employed as positive electrode in the electrolysis of strong aqueous hydrofluoric acid, the immersed portion swells up, becomes pappy, and quickly disintegrates; and the disintegrated portion, when purified in the manner above described, forms a black powder, which swells up considerably when heated, is insoluble in all solvents, and contains carbon, oxygen, hydrogen, and fluorine.—(2). *Electrolysis of Potassium Antimonate:* When a solution of this salt, obtained by heating the acid antimonate in large excess with caustic potash-lye, is decomposed by a battery of eight Bunsen's elements, the positive electrode being formed of wood-charcoal or retort-carbon, large quantities of gas are evolved at the negative electrode, and only a small quantity at the positive, which at the same time is strongly attacked, while the electrolyte becomes deep black, and deposits a black sediment, Ω, soluble in a large quantity of water. On filtering the liquid, adding the black wash-waters of the precipitate Ω, then concentrating on the water-bath, and adding excess of hydrochloric acid, a copious precipitate, B, is formed, which, after washing and drying, contains only traces of antimony, and exhibits the following properties:—1. After drying at 100degs. it contains carbon, hydrogen, oxygen, and antimony. 2. It dissolves in water and in alkaline hydrates, forming deep black solutions, from which it is completely precipitated by mineral acids. 3. It dissolves with rise of temperature in aqueous potassium hypochlorite, forming mellic acid and other benzocarboxylic acids, together with potassium antimonate. This substance being analogous in modes of formation and in properties to mellogen, the authors distinguish it by the name of *Stibiomellogen*. When graphite is used as positive electrode in solutions of potassium antimonate, large quantities of gas are likewise evolved at the negative, and very little at the positive electrode. At the end of the experiment, the graphite is found to be much disintegrated, and a copious black deposit, Ω, is found at the bottom of the voltameter, surmounted by a nearly colourless liquid containing small quantities of mellic acid and its derivatives. The deposit Ω, after washing and drying, is found to consist of a mixture of graphite and a new compound of carbon, hydrogen, oxygen, and antimony, which the authors designate as *Stibiographic acid*. Its composition and properties will form the subject of a future investigation. From the results obtained in this and in preceding investigations, the authors infer: (1). That in the electrolysis of nitric, phosphoric, arsenic, and antimonic acids and their salts, the first and third yield with electrodes of wood-charcoal or retort-carbon mellogen free from nitrogen and arsenic—whereas with graphite electrodes they yield graphite free from nitrogen or arsenic—and that the second and fourth give with charcoal or retort-carbon electrodes, phospho- and stibio-mellogen respectively—whereas with graphite electrodes they give phospho- and stibio-graphitic acid.

ELEMENTARY ELECTRICITY.—XII.

(CONTINUED FROM PAGE 79.)

All bodies possess a certain amount of resistance, and only a certain amount, though the interval between the best conductors (such as copper) and the best insulators, or worst conductors, such as sulphur or paraffin wax, is very great indeed. The resistance of a bar of glass is not less than 600,000,000,000,000,000,000,000,000 times that of a bar of copper of the same dimensions.

The first measurements of the resistance of conductors were made by Henry Cavendish, who not only compared the resistance of metallic wires but also of liquids (electrolytes), especially of solutions of common salt. These measurements were undertaken mainly in connection with his experiments on the torpedo, which led to the measurement of the resistance of sea water. From Cavendish's results it appears that the conductivities of saline solutions of different strengths are nearly proportional to the per centage of salt present, a fact recently rediscovered by Kohlrausch. Though Cavendish employed a Leyden jar for his source of electricity, and measured the resistance of the conductor simply by sending the charge of the jar through the conductor and his own body, and estimating the intensity of the shock; his results, so far as they apply to solutions of salts, were not improved upon until Kohlrausch took up the matter in 1857. Cavendish appears to have understood the theory of divided circuits and practically to have arrived at Ohm's law, though he did not formally enunciate the law.

The relation between the electromotive force in a circuit and the current produced by it is expressed by Ohm's law. As ordinarily enunciated this law is as follows:—

The current in any conductor is equal to the electromotive force between its extremities divided by its resistance.

From this it follows that the current in any simple circuit is equal to the whole E.M.F. around the circuit divided by the whole resistance of the circuit.

Ohm's law may be converted into the following statements:

The resistance of a conductor is equal to the electromotive force between its extremities divided by the current produced in it.

This statement furnishes what may be called a *quantitative* definition of resistance, or a definition of the measure of resistance, since current and electromotive force are both quantities which we already know how to measure. The definition previously given may be regarded as a *qualitative* definition of resistance telling us what kind of quantity resistance is, but not enabling us to measure it.

The unit of resistance is the resistance of a wire in which a unit electromotive force produces a unit current. The unit of resistance adopted in practice is called an ohm.

It may appear at first sight that Ohm's law *simply* gives a definition of the measure of resistance, and this is all that is formally stated; but, as in Newton's laws of motion, there is more implied in the law than appears on the surface. The fact that resistance is an attribute which may be assigned to a conductor without qualification as regards the current flowing in it implies that the resistance of a conductor is constant so long as its temperature, mechanical condition, &c., remain unchanged. Hence, in the same conductor the current will be proportional to the electromotive force between its extremities. Therefore, if the E.M.F. be doubled, the current also will be doubled, and so on, and this is the law implied in the statement.

The clearest conception of the meaning of Ohm's law may, perhaps, be gained by considering what is implied in its denial. Thus, if we deny that the current is proportional to the electromotive force, we may hold that, if the E.M.F. is increased, the current will be increased in a higher or in a lower ratio. Both these views have been maintained. According to the first hypothesis, the resistance of a conductor will diminish as the current in it is increased, as though the increased E.M.F. partially broke down the resisting power of the conductor. According to the second hypothesis, the resistance will increase with the increase of the current. Now, the measurement of the resistance of a conductor is an operation which can be carried to a higher degree of accuracy than any other physical measurement, except, perhaps, the measurement of mass by weighing. Thus, the equality of the resistances of two wires can be ascertained to within one part in a million. It is therefore possible to apply very severe tests to Ohm's law, but the law holds good under the most severe tests which have yet been applied.

When a current flows along a wire and can only enter or leave the wire by the ends, there will be the same current across every section of the wire. If the wire be of the same material throughout and of uniform thickness, there is no reason why the potential should fall more rapidly in one part of the wire than in another. Thus, there will be a steady fall of potential at a uniform rate, from the end at which the current enters to that at which it leaves the wire. Hence, the difference of potential between any two points in the wire is proportional to the distance between the points. But the current in every portion of the wire is the same; hence, for any length of the wire the difference of potential between its extremities is proportional to its resistance, and therefore the resistance of any portion of the wire is proportional to its length.

If the resistances of a round wire and a ribbon of the same material and having the same sectional area be compared, they will be found to be the same, length for length, but if the sectional area be the same, the surface of the flat ribbon will be very much greater than that of the round wire. Hence, it follows that the resistance of a wire depends on its sectional area and not on its surface, and the conduction of electricity is a phenomenon which takes place uniformly throughout the substance of a conductor and not on its surface. It follows, therefore, that two wires of the same length, material, and section, placed side by side, and having both their extremities joined, will be electrically equivalent to a single wire of double the sectional area of either, and so on. But if a given electromotive force act between their extremities, the two wires will carry twice the current that either wire would carry, and so on if there are more than two wires. Hence, the resistance of the compound conductor will be inversely proportional to the number of wires. It follows, therefore, that the resistance of a single wire of given length and material will be inversely proportional to its sectional area. Hence:—

The resistance of a conductor of uniform section is directly proportional to its length, and inversely proportional to its sectional area.

So far we have considered the current per unit area of the section of the conductor to be always the same. The true test of Ohm's law lies in altering the strength of the current per unit area of the conductor, or what may properly be called the *intensity* of the current, and ascertaining whether the resistance of the conductor as measured by the ratio of the electromotive force between its extremities to the current produced remains the same. A very simple method of carrying out this experiment was proposed by Clerk Maxwell, and the measurements were carried out by Professor Chrystal. Five coils, which we may call A, B, C, D, and E, were wound so that each had as nearly as possible the same resistance (viz., 30 ohms). The equality of their resistance was first tested, and the small differences found were registered for the correction of the final result. The coils A and B were connected in series, that is, end to end, so that the same current flowed through each in succession; C and D were similarly connected, and the two compound conductors were then connected in multiple arc or parallel circuit, that is, so that the current could divide itself, and part flow through A and B, the other part flowing through C and D. The resistance of the four conductors so connected was then compared with that of the single coil E by the Wheatstone bridge method, which will be explained later on. In this arrangement the electromotive force between the extremities of any of the coils A, B, C, or D is clearly one-half that between the extremities of the compound conductor; that is, one-half of that which would exist between the extremities of the coil E, if the latter were put in the

Digitized by Google

place of the compound conductor. If Ohm's law be true, but not otherwise, the current through each of the coils of the compound conductor will be half that which would flow through the single coil E, and hence the whole current through the compound conductor, since it possesses two branches, will be the same as through a single coil with the same E.M.F. between its extremities. Hence the resistance of the compound conductor will be the same as that of a single coil. By an ingenious arrangement, it was possible to compare any one of the five coils with the other four arranged as above described, and although a difference of resistance of one part in 500,000 could easily be detected, no error could be found in the accuracy of Ohm's law.

But a much more severe test, based upon the same principle, was applied to Ohm's law by Professor Chrystal. Instead of employing a combination of four equal coils, which are simply equivalent to a single wire of double length and double section, and comparing this with a coil equal to each of the four, Professor Chrystal employed two wires, one long and thick, the other short and very thin. By means of a rapid commutator of special design, he compared the resistances of these two wires in rapid succession when very feeble currents were passing through them, and when very strong currents were passing, and found the ratio of the resistances the same in the two cases. The strong currents raised the temperature of the fine wire to bright redness, but the feeble currents were sent through before the wire had time to cool, and then the strong currents again. The resistances of the wires bore the same ratio to each other for both sets of currents.

Def. The conductivity of a conductor is the inverse of its resistance, *i.e.*, if the resistance be denoted by R the conductivity will be represented by $\frac{1}{R}$.

When a number of conductors are connected so that the same current flows through each in succession, they are said to be arranged *in series*, and the *resistance* of the compound conductor is the sum of the resistances of its constituents.

When a number of conductors are so connected that the current divides itself between the conductors, part flowing through one and part through another, they are said to be arranged *in multiple arc*, and the *conductivity* of the compound conductor is the *sum of the conductivities* of its constituents.

Thus, if conductors whose resistances are R_1, R_2, R_3 . . . are arranged in series, the resistance of the system will be $R_1 + R_2 + R_3 + \ldots$. If they are arranged in multiple arc, the conductivity of the system will be

$$\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots .$$

and its resistance will be

$$\frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots} .$$

A number of battery cells are said to be arranged in series when the same current flows through each in succession, the zinc of one cell being connected to the copper (platinum, carbon, &c.) of the next, and so on. In this case the electromotive force of the batery is the sum of the electromotive forces of the several cells, while its resistance is the sum of their resistances.

A battery is connected in multiple arc when all the zinc plates are connected together as well as all the copper (platinum, carbon, &c.) plates, so that the current is divided between the cells. If all the cells have the same E.M.F. and the same resistance, the E.M.F. of the battery will be equal to that of one cell, while the resistance will be inversely proportional to the number of cells.

Sometimes a battery is so connected that several sets of cells are connected in series, and the several series then treated as single cells and connected in multiple arc. Suppose there are *nm* cells, each of electromotive force E and resistance *r*, and that they are arranged in *m* series, each series containing *n* cells, and let the *m* series then be connected in multiple arc and the terminals of the battery connected by an external conductor of resistance R. The E.M.F. of each series of *n* cells will be *n* E, which will therefore be the E.M.F. of the whole battery. The resistance of each series will be *nr*, and therefore the resistance of the whole battery will be $\frac{nr}{m}$. Hence the resistance of the whole circuit will be $\frac{nr}{m} + R$, and by Ohm's law the current C will be given by the equation,

$$C = \frac{nE}{\frac{nr}{m} + R}$$

The quantity $\frac{nr}{m}$ is sometimes called the *internal* resistance of the battery, while R is called the *external* resistance of the circuit. For a given number of cells—that is, for a given value of *nm*—the current will be greatest when the external and internal resistances are as nearly as possible equal.

Thus, if there is a battery of 80 Grove cells, each having a resistance of ·2 ohm (the ohm is a unit of resistance to be defined later on), and it is desired to send a current through an electro-magnet having a resistance of 1 ohm, the best arrangement will be to set up the battery in four series each of 20 cells. The resistance of each series will then be 4 ohms, and that of the whole battery 1 ohm, that of the whole circuit being 2 ohms, while the E.M.F. will be 20 E (the E.M.F. of a single cell being denoted by E), and the current will be 10 E.

If the battery is arranged so that all the cells are in series the E.M.F. will be 80 E, the internal resistance 16 ohms, and the current will therefore be $\frac{80\,E}{17}$.

If the battery be all in multiple arc the E.M.F. will be E and internal resistance $\frac{1}{400}$ ohm. Hence the current will be $\frac{E}{\frac{1}{400} + 1}$ or $\frac{400\,E}{401}$.

If the battery be arranged in 16 series of 5 cells each, the resistance of each series will be 1 ohm, the resistance of the whole battery $\frac{1}{16}$ ohm, and its electromotive force 5 E. Hence the current will be $\frac{5\,E}{1\frac{1}{16}} = \frac{80\,E}{17}$, which is the same as when the battery is all in series.

Comparing the four cases we have for the several currents $10\,E, \frac{80\,E}{17}, \frac{400\,E}{401}$, and $\frac{80\,E}{17}$. These are in the ratios of $\frac{1}{40} : \frac{1}{85} : \frac{1}{401} : \frac{1}{85}$.

When a number of battery cells are connected in multiple arc, or, as it is sometimes expressed, in parallel circuit, so that the conductivity of the battery is the sum of the conductivities of the several cells, while the electromotive force of the whole battery is simply that of one cell, the battery is sometimes said to be arranged "*for quantity.*" This is because the battery is capable of sending a very great current through a short thick wire of very small resistance, for though the E.M.F. is only that of one cell the circuit possesses such a small resistance that the current is very great. The whole arrangement is analogous to a very large channel which is capable of delivering a very great quantity of water per minute, though the head of water may be very small.

When the cells of a battery are connected in series, so that the resistance of the battery is the sum of the resistances of the several cells, while the E.M.F. of the battery is the sum of the electromotive forces of the cells, the battery is sometimes said to be arranged *for intensity.* Such an arrangement can send a considerable current through a conductor of great resistance, as, for example, a long telegraph line; but a battery arranged in this way is not capable of sending so great a current through a wire of very small resistance as when the cells are arranged in "multiple arc." If we wish to pump a stream of water through a very great length of

very fine tube, a pump with very small suction and delivery valves, and worked at very high pressure, will be best suited to our purpose; but if we wish to pump a great body of water through a comparatively short length of pipe of great diameter, we must select a pump with very large valves, though the pressure at which it is worked may be much less than in the former case, otherwise the "internal resistance" of the pumps will prevent our obtaining more than a very small stream of water, notwithstanding the low resistance of the pipes. As before stated, a given number of battery cells will produce the greatest current in a given conductor when the cells are so arranged that the "internal resistance" of the battery is equal to the resistance of the external conductor.

Though we may speak of a battery arranged "for quantity" or "for intensity," we must avoid the error of speaking of "quantity currents" and "intensity currents." A current is completely defined by the number of units of electricity which pass across any section of the conducting circuit in a second, and two currents can differ from one another only in this respect. The one current may be produced by a high electromotive force in a circuit of great resistance, and the other by a comparatively low electromotive force in a circuit of correspondingly low resistance, but if the total quantity of electricity passing per second in each circuit is the same the currents are equal. If in some parts of the circuit the conductor is very thin, and at other parts very thick, the amount of current *per unit area of the section of the conductor* will differ in different parts, and we may regard the current as more *intense* when the section of the conductor is smaller, but using the word in this sense the same current may have a high intensity in one part of the circuit and a low intensity in another. This is the sense in which we have above used the word intensity as applied to currents of different strengths per unit area of the section of the conductor, but it is not the sense in which the phrases "intensity currents" and "quantity currents" have been generally, but erroneously, employed.

CURRENT ENERGY.—V.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 437, VOL. X.)

The mechanical forces between conductors carrying currents, the induction of currents, Joule's law of the generation of heat, and the principle of the conservation of energy are all intimately connected. We cannot, in fact, isolate the mechanical forces from the induced electromotive forces without setting up artificial barriers, to be afterwards taken down. Yet it is necessary, since we cannot treat every part of a subject at the same time, to make a beginning somewhere, by selection of some facts and temporary exclusion of others, and the question presents itself, where to make a starting point for the induction of currents from the theoretical point of view. It is not so much a question of what are the laws of induction, though they are of course involved in the matter, as how to exhibit them and their connections with other electro-magnetic phenomena in a complete theory based upon the simplest and least number of experimental laws, and in what order to take the latter.

Now, in building up a consistent theory to embrace a number of facts of a certain class (complete relatively, that is to say, by a process of abstraction) there may be a large choice of methods. As all roads were said to led to Rome, so all truth is consistent, and by however roundabout a method we go to work we shall arrive at the same results on the way or in the end, if we are working correctly and not trusting to unsound hypotheses. From a group of experimental facts we may divine a certain relation, and by generalising it from the particular cases observed, make it a law, empirical so far, *i.e.*, not deducible from previously known laws at the time, though it may become so later. Such a law is that of gravity, though so long since its discovery it has not been satisfactorily explained by more easily understood laws. Ohm's law is also without explanation, whilst, on the other hand, the gaseous laws have been explained dynamically, as Newton's law of gravity and Ohm's law may be some day.

In general several such experimental laws are required to form the framework of a complete theory, though two or three may suffice to make considerable progress. Thus in electrostatics, after learning that electricity is a physical magnitude capable of measurement, that charges may be added and subtracted, the addition to this of the law of force between two concentrated charges, as ascertained by means of Coulomb's torsion balance, generalised to apply to all cases of electricity distributed in a single dielectric, enables us to at once apply the theory of the potential in its general aspect, and to find the distribution of force and the potential energy in the case of any arbitrary distribution of electricity. Add to this, further, the division of bodies into conductors and non-conductors, thus necessitating that in a state of electrical equilibrium there can be no electric force in any part of a conductor, and that therefore the potential of each insulated conductor or of each group of conductively-connected conductors must be a constant, and we have the means of determining the distribution of electricity in practical cases. To this add the further law relating to the difference of capacity of different dielectrics, and we are enabled to calculate the modifying influence on the field of force produced by varying dielectric capacity, and we have got nearly as far as the mathematical theory of electrostatics goes at present. There are plenty of facts outside the theory, but so far as it goes it is complete and consistent, and the facts excluded relate in the main to phenomena observed during the change from one state of equilibrium to another, on the borderland between purely static and purely dynamic phenomena.

Now, we might arrive at just the same results by other methods. Thus, in the theory of the influence of varying dielectric capacity above mentioned, instead of putting Faraday's law at once into a mathematical form, and starting with it, as Sir W. Thomson long ago did (introducing the dielectric constant K into the potential and force equations), we may try to do without it by assuming that the law of force between two charges is exactly the same for any dielectric, but that there are an immense number of small conducting particles embedded in a dielectric. After long travail, we shall find that this hypothesis leads eventually to Faraday's law. The hypothesis may be really true, but the mathematical theory is much simpler without it altogether.

There is an analogous case in the theory of induced magnetisation. The simplest method of laying down the theory is to start with Faraday's idea that different bodies conduct magnetic force differently, and to at once introduce a co-efficient to express this conductivity (the magnetic permeability, &c.). Calling the magnetic force as thus modified, that is $\mu \times$ force, the magnetic induction, we find that the induction is a flux of no convergence, or is distributed in closed tubes, and we have magnetic force producing magnetic induction in heterogeneous media, just as electromotive force produces current in similarly heterogeneous conducting media. But we may arrive eventually at the same result, which Maxwell thought best represented Faraday's ideas, by making the induced magnetisation the object of attention in the first place, and not the magnetic induction.

In these and similar cases the best course to pursue is to adopt that initial hypothesis which leads to the general results in the most direct manner, provided, of course, the hypothesis be free from objection.

In the theory of electro-magnetism, there is considerable choice of methods. As regards the electro-magnetic forces alone, we may find a law of force between a pair of current elements which will enable us to deduce the force acting upon any complete circuits. The investigations concerning the imaginary force between a pair of elements are usually very complex, and there is besides a grave objection. For we have no reason to believe that current elements can be isolated in the same way as charges of electricity may be (viz., on insulated conductors separated by a dielectric from all other charges). The current elements of course exist, but never independently of all other elements, if currents are always closed. As a consequence, there is an indefinite choice of formulæ for the

Digitized by Google

force between a pair of elements, which is essentially indeterminate, a definite formula being obtainable only by making some pure assumption.

But a knowledge of the force in question is not required, even if it could be definitely found, and it is preferable to start with closed circuits and keep to closed circuits. Thus, all the mechanical forces between currents and currents, and currents and magnets may be based upon the law of the equivalence of a small closed current and a little magnet as regards the forces they exert; or we might do without the magnet altogether. Then, with a knowledge that currents are quantitatively expressible, have direction, and follow closed paths, we may, by geometrical or analytical reasoning regarding the properties of lines and surfaces, deduce all the rest, aided in particular by Ampère's device, whereby a finite linear circuit is replaced by any number of other circuits forming a network externally bounded by the original circuit, a process which has many important applications, and is of great assistance in various complex questions. Without further laws to help us, for we have no corncern with *how* the currents are obtained, we can develop the whole theory of the quantitative and directional relations of current and magnetic force, and of the v.-potential of current, and calculate the electro-magnetic forces, and the potential energy of any distributions of current, with respect to those forces. As regards a pair of linear currents, we find that the forces between the conductors may be found from a scalar function whose value depends upon the size, forms, and relative position of the circuits, multiplied by the strengths of the currents, say $M\,C_1C_2$, where M is the function mentioned. The mutual potential energy of the two currents is $-M\,C_1C_2$, and its rate of decrease as the circuits are shifted measures the rate of working of the electro-magnetic forces during the displacement, and consequently the forces concerned. The most readily intelligible form for the potential energy is in terms of the amount of induction or number of lines of induction through the circuits. The unit current in the first circuit sends the same amount of induction through the second as the unit current in the second does through the first, and this quantity is the M in the potential energy, reckoning the positive direction through a current to be that in which a free N. pole would travel through it under the action of its magnetic force.

From a pair of linear circuits we easily pass to the case of any distribution of currents, and we find the potential energy of two systems C_1 and C_2 to be $-$ T, where

$$T = \frac{1}{2}\Sigma\,\overline{A_1C_1} + \frac{1}{2}\Sigma\,\overline{A_2C_2} + \Sigma\,\overline{A_1C_2}$$

$$= \frac{1}{2}\Sigma\,B_1^2 + \frac{1}{2}\Sigma\,B_2^2 + \Sigma\,\overline{B_1B_2}$$

where A_1 and A_2 are the v.-potentials, and B_1, B_2 the magnetic forces, and space is divided into volume elements. But the most convenient form for two linear circuits is

$$T = \frac{1}{2}L_1C_1^2 + \frac{1}{2}L_2C_2^2 + M\,C_1C_2$$

where M is the same quantity as before, and L_1 L_2 are the corresponding quantities for the circuits taken separately. C_1 and C_2 are now the integral currents, not the current densities.

We have now to take down the artificial barrier set up in dealing with the electro-magnetic or mechanical forces. The currents were presumed to be given constant, and to remain constant during relative motion, and although work done by the electro-magnetic forces has been estimated, no account has been taken of other work in the system, as in keeping up the currents, or of the principle of conservation of energy. But currents do not remain in general of constant strength when in motion in a magnetic field, the changes in the currents being the induced currents, and it becomes absolutely necessary to enlarge the field of view.

There are several methods of laying down the laws of induced currents. If we were to choose that method which leads most easily and directly to the required laws, we should employ Maxwell's dynamical method, which exhibits the whole subject in a concise and comprehensive manner, whilst both the electro-magnetic actions and the electromotive forces of induction are deduced in the simplest possible mode. But it can scarcely be said that the cardinal assumptions of the dynamical method, that the energy of a current system is kinetic energy, that the system is a dynamically connected system, in which currents correspond to velocities, and that the expression for the energy does not contain products of the velocities of the geometrical and the electric variables, are sufficiently simple to justify us in selecting the method to start with. The dynamical method should rather follow other methods, which, if less direct, are more easily understood in the earlier stages.

The laws of induction were first completely quantitatively established by J. Neumann, who took for his basis Lenz's law, which was a generalisation from a comparison of the results of obtaining induced currents by the relative motion of a circuit (the secondary), without a permanent current, and of a primary circuit containing a current kept up by a battery. Now, if we grant that a current is induced in the secondary by relative motion of the circuits, it must be in either one direction or the other, and the electro-magnetic action set up between the induced and the primary current must, therefore, be such as either to resist or assist the motion. If the latter were the case, it would follow that the secondary circuit, when at rest, and with, therefore, no current in it (the primary being also supposed at rest), and with no force acting on it, would be in unstable equilibrium. For the least displacement of the secondary circuit, either to or from the primary, would call up forces increasing the displacement, and the secondary would continue to approach or retreat from the primary circuit, according to its initial motion. Such a state of unstable equilibrium being plainly inadmissible, it follows that the direction of the induced current, if there is any, must be such that the mutual forces between it and the primary resist the motion. This principle, applied to the motion of either primary or secondary, constitutes Lenz's law.

In reference to Neumann's investigations, Maxwell remarked that a step of still greater scientific importance was soon after made by Helmholtz and Sir W. Thomson, who showed that the induction of currents could be mathematically deduced from the electro-magnetic actions of Oersted and Ampère by the application of the principle of the conservation of energy.

But it must not be concluded from this that, given the electro-magnetic forces, and the truth of the general principle named, nothing more is needed to build up the whole science of the induction of currents. The statement sometimes made that the laws of induction follow of necessity from Ampère's forces and conservation is of too broad a nature. If we modify the statement, and say that the laws of induction are consistent with Ampère's actions, and with conservation, there will be nothing to be objected to. That this is not a mere difference of tweedledum and tweedledee may be easily seen from the history of the subject, if it is not sufficiently evident by itself. We may, indeed, from the existence of Ampère's forces, and a conviction of the truth of the conservation principle, conclude certainly that some other actions occur, but the principle merely asserts that energy is never lost, that energy put into a system from outside must necessarily be either stored up or make its appearance somewhere in some form or other; but what the form may be depends upon the mechanism, on the dynamical connections, and conservation does not tell us what they are, nor what will happen. There must be other information given.

(TO BE CONTINUED.)

Electric Lighting for Westminster.—A memorial has been addressed to the vestry of St. James's, Westminster, in favour of the granting of a provisional order to light a certain portion of the district by electric light to the Telegraph Construction and Maintenance Company, and not to the Edison Electric Light Company.

CITY AND GUILDS OF LONDON INSTITUTE FOR THE ADVANCEMENT OF TECHNICAL EDUCATION.

TECHNOLOGICAL EXAMINATIONS, 1883.

22B.—ELECTRIC LIGHTING AND TRANSMISSION OF POWER.

Examiner, Prof. AYRTON, F.R.S.

Instructions.

This examination is for the purpose of ascertaining whether the candidate has intelligently studied the methods of constructing and using the machinery employed in the production and transmission of electric power, and whether he has endeavoured to ascertain the scientific reasons underlying the processes adopted.

The candidate must confine himself to one grade only, the ordinary, or honours, and must state at the top of his paper of answers which grade he has selected. He must not answer questions in more than one grade.

If he has already passed in this subject in the first division of the ordinary grade he must select his questions from those of the honours grade.

The number of the question must be placed before the answer in the worked paper.

Each candidate is supplied with a sheet of ruled squared paper to be used for plotting curves only.

Three hours allowed for this paper.

Ordinary, or Pass Grade.

[Candidates are not expected to answer more than six questions, but more may be attempted.]

1. What is meant by electromotive force? Distinguish between a voltameter and a voltmeter. A voltameter is joined up in series with an electro-magnet, and various currents are successively sent through the two instruments; compare the action in the voltameter with the force necessary to detach the armature of the electro-magnet for the various currents.

2. Without going into details as to how resistances are practically measured, explain accurately what is meant when it is said that one resistance is ten times as great as another.

3. Define an ohm, ampere, volt, coulomb, and farad. What current will 12 Daniell cells, arranged 4 in series and 3 in parallel, send through a galvanometer of 50 ohms resistance, shunted with a resistance of 10 ohms, if the cells have each 3 ohms resistance and the wire joining the battery with the galvanometer has a resistance of 5 ohms?

4. What is the principle of a dynamo? Explain in detail the construction of the dynamo with which you are best acquainted, describing the nature of the material (soft iron, cast iron, or steel, &c.) employed in each part, and give full sketches illustrating the mode of winding the coils, and the size and shape of each part of the machine, as well as the reasons for the method of manufacture employed.

5. Explain the difference between a "series" dynamo and a "shunt" dynamo, and give drawings showing the mode in which the wires are wound in each machine.

6. Distinguish between the electromotive force of a dynamo and the potential difference at its terminals. Explain how the electromotive force and the potential difference at the terminals vary with the external resistance—first, in a "series" dynamo, secondly, in a "shunt" dynamo.

7. What is meant by the "efficiency" of an incandescent lamp? Why does the efficiency increase with the current sent through it? State what practical results have been obtained connecting the efficiency of a carbon filament with its life. Give the "efficiencies" of the various incandescent lamps you are acquainted with when glowing with their normal currents.

8. What is the principle of a "speed indicator" and a "speed counter?" Give drawings.

9. Define a "watt." Give a drawing and description of a "watt meter."

10. What is meant by the "lead" given to the brushes in a dynamo? Show, with sketches, the lead that should be given in a dynamo, and in the same machine when run as a motor, and give your reasons. Explain how the lead must be adjusted for speed and for current, first, in a "series," secondly, in a "shunt" dynamo.

11. Give a table of the safe currents that may be sent through copper wires of various gauges. What percentage loss of potential is there when 50 amperes is sent through 100 yards of copper wire $\frac{1}{8}$th inch in diameter if the initial potential is 110 volts? A foot of copper wire $\frac{1}{1000}$th of an inch in diameter has about 10 ohms resistance at 0° C.

Honours Grade.

[Candidates are not expected to answer more than seven questions, but more may be attempted.]

1. What is meant by electromotive force? Distinguish between a voltameter and a voltmeter. A voltameter is joined up in series with an electro-magnet, and various currents are successively sent through the two instruments; compare the action in the voltameter with the force necessary to detach the armature of the electro-magnet for the various currents.

2. Without going into details as to how resistances are practically measured, explain accurately what is meant when it is said that one resistance is ten times as great as another.

3. Define an ohm, ampere, volt, coulomb, and farad. What current will 12 Daniell cells, arranged 4 in series and 3 in parallel, send through a galvanometer of 50 ohms resistance, shunted with a resistance of 10 ohms, if the cells have each 3 ohms resistance and the wire joining the battery with the galvanometer has a resistance of 5 ohms.

4. What is meant by the characteristic curve for a dynamo? Draw the curve for a series Gramme, and explain what practical use can be made of it. Draw the actual curve connecting the potential difference at the brushes of the shunt dynamo with which you are best acquainted, with the current flowing in the external circuit.

5. Explain the general principles of the methods that have been designed to keep the potential difference between electric mains constant and independent of the current required. Give full details of that one of the systems with which you are best acquainted.

6. Explain fully why the electromotive force in a dynamo run at constant speed falls off for increase of current after the current has reached a certain limit.

7. Describe fully with drawings the various methods that have been designed to cause an electro-motor to run at a constant speed, whatever work it may be doing.

8. A certain motor, in which the armature and field magnet have each a resistance of 0·1 ohm when run at 1,000 revolutions a minute, produces 1 horse-power when a current of 30 amperes flows through the motor, and a potential difference of 45 volts is maintained at its terminals. What should be the resistance of the armature and field magnet of the same motor, so that it will produce 1 horse-power when run at the same speed, and when a potential difference of 200 volts is maintained between its terminals, the efficiency of the motor remaining the same?

9. You are required to design and fit an electro-motor to a tramcar. Write out the advantages and disadvantages you see in the three following methods: (1) A rapidly turning motor attached to the ordinary tramcar wheels, with some speed-reducing gear; (2) a rapidly turning motor attached to a driving wheel of small diameter, without speed reducing gear; (3) a motor attached directly to the ordinary wheels and only turning as fast as they ordinarily do. Select that one of the methods which you consider the best, and give sketches of the exact way in which you would carry it out.

10. Write a short essay, showing what has been practically done in electric transmission of power, giving figures, &c., to show the amount of power transmitted, the efficiency obtained, the practical difficulties that have been met with, &c.

22C.—ELECTRICAL INSTRUMENT MAKING.

Instructions as for 22B.—Ordinary, or Pass Grade.

[Candidates are not expected to answer more than six questions, but more may be attempted.]

1. What is meant by electromotive force? Distinguish between a voltameter and a voltmeter. A voltameter is joined up in series with an electro-magnet and various currents are successively sent through the two instruments. Compare the action in the voltameter with the force necessary

Digitized by Google

to detach the armature of the electro-magnet for the various currents.

2. Without going into details as to how resistances are practically measured, explain accurately what is meant when it is said that one resistance is ten times as great as another.

3. Define an ohm, ampere, volt, coulomb, and farad. What current will 12 Daniell cells, arranged 4 in series and 3 in parallel, send through a galvanometer of 50 ohms resistance, shunted with a resistance of 10 ohms, if the cells have each 3 ohms resistance and the wire joining the battery with the galvanometer has a resistance of 5 ohms?

4. Describe the best practical method for magnetising steel bar magnets so that they may be regularly magnetised.

5. What is meant by "calibrating" a galvanometer? Describe the various methods of calibrating that may be employed.

6. A foot of copper wire, $\frac{1}{1000}$th of an inch in diameter, has about 10 ohms resistance at 0°C; what then will be the resistance of a wire of No. 16 gauge (having about $\frac{1}{16}$th inch diameter) of the proper length to fill a bobbin, whose height inside the endcheeks is 3 inches, external diameter 2 inches, and the diameter of whose core is $\frac{3}{4}$ inch? How much will the resistance be altered if the temperature be raised to 20°C, and in which direction will it be altered?

7. Explain how the heat produced in a coil by a current passing through it is connected with its magnetic effect. A certain bobbin of wire through which a current is passed is found not to produce sufficient magnetic effect when the current is so strong as to heat it to a limit of safety. Is it possible by altering the gauge of wire employed to increase the magnetic effect without increasing the temperature of the coil?

8. You are desired to construct a glass Leyden jar with very high insulation; explain by means of sketches exactly how you would accomplish this. Give a sketch of an insulating stand with high insulation.

9. Give a drawing of a shunt box having high insulation. Prove what should be the resistance of three shunts, so that when respectively used, $\frac{1}{10}$th, $\frac{1}{100}$th, $\frac{1}{1000}$th of the total current passes through a galvanometer of 5,000 ohms resistance. What kind of wire would you use for the shunts; how would you wind it; and where would you place it to diminish the temperature error as much as possible?

10. What is meant by a "dead beat" galvanometer? Give a drawing of one. Describe in detail the construction of a galvanometer used to measure a a current absolutely.

Honours Grade.

[Candidates are not expected to answer more than seven questions, but more may be attempted.]

1. What is meant by electromotive force? Distinguish between a voltameter and a voltmeter. A voltameter is joined up in series with an electro-magnet and various currents are successively sent through the two instruments. Compare the action in the voltameter with the force necessary to detach the armature of the electro-magnet for the various currents.

2. Without going into details as to how resistances are practically measured, explain accurately what is meant when it is said that one resistance is ten times as great as another.

3. Define the ohm, ampere, volt, coulomb, and farad. What current will 12 Daniell cells, arranged 4 in series and 3 in parallel, send through a galvanometer of 50 ohms resistance, shunted with a resistance of 10 ohms, if the cells have each 3 ohms resistance and the wire joining the battery with the galvanometer has a resistance of 5 ohms?

4. Calculate the capacity in microfarads of a condenser composed of two plates, each $1\frac{1}{2}$ metre long, 65 centimetres wide, placed parallel to one another at a distance of 0·2 millimetre apart. 1 farad equals 9×10^{11} C.-G.-S. electrostatic units of capacity.

5. Describe in detail the construction of an artificial cable, and the methods you would employ for testing it.

6. What is the best method for preventing the bad effect of damp on resistance coils? In order to make a resistance box to measure anything from 1 to 10,000 ohms, what is the least number of coils that must be employed, and what are their respective resistances?

7. Explain in detail how an electromotive force can be measured absolutely by weighing.

8. An ebonite rod, 3 inches high, carrying a binding screw at the top, has to be fastened to a wooden board by a screw passing through the board. Show, by means of a sketch, what shape you would give to the ebonite rod to obtain the maximum insulation, and mention what is the fault usually made and which is especially to be guarded against in fixing the rod to the board.

9. What is the law connecting the strength of a straight electro-magnet with its length, the diameter of the core, the number of turns of wire and the current? Explain what are the limitations, and the reason of such limitations, in the use of your formula. Compare the strength of an electro-magnet when wrought iron, cast iron, and steel are respectively used for the core, other things remaining the same.

10. If the diameter of the coil of an electro-magnet is fixed, prove what is the best diameter to give to the iron core. Show whether the same rule holds if the diameter of the core be fixed, whilst that of the coil is variable.

ELECTRICAL MACHINES AND THE TRANSMISSION OF POWER.

(Translation.)

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I do not know what answer my honoured antagonist, Mr. Kapp, will make to the letter which you were good enough to insert in *The Electrician* for May 19th last. I do not even know whether Mr. Kapp will deign to reply to this letter; but, in any case, I do not wish to delay any longer in expressing my gratitude for the kindness you have vouchsafed to my labours in the columns of your esteemed publication. In pursuance of this line of thought I cannot do better than demonstrate to you that the ideas I have put forward, and which you have thought to be of some interest, are not as baseless as has been stated. I will therefore justify the reception you have been good enough to accord to my two letters.

What appears to exasperate Mr. Kapp, whose authority in matters scientific I am fully cognisant of, is that I have been bold enough to presume that "it may perhaps be possible to use receivers without wire in the magnetic field that can be subject to induction." Now, the last number of *Engineering* mentions an electro-motor, patented by M. Immisch, of London, which is nothing more or less than a machine *without wire in the magnetic field that can be subject to induction*, and, moreover, seems to be a very good machine. The English have not got the name of being very unpractical people, and when they take out a patent it generally has its *raison d'être*. I conclude that I was not far from some such conception, and that you may perhaps have done good in giving it a place.

When I wrote my first letter of the 13th April, I evidently had no knowledge of this patent of M. Immisch's, which was only published in *Engineering* of the 18th May; further, the machine which I have made a study of does not resemble that of this inventor. It has been sufficient for me to show you that I have not been guilty of a joke, which would, in any case, be out of place in the columns of a scientific and widely circulated journal such as yours, in speaking of machines "*without wire in the magnetic field that can be subject to induction.*" [*Sans fil de l'induit, dans le champs magnétique.*]

Your translator has not yet succeeded in giving a perfect rendering of the sense of this phrase; however, it is comprehensible to those who do not wilfully misread it, and I again thank you for having translated my letter so well.

Perhaps I may be able at some future time to submit to you a complete description of the system of transmission that I have conceived; my labour can be examined by any competent persons, and if it is considered worth anything I shall endeavour to make it known in England.—Yours, &c.,

A. Bandsept,

May 26, 1883. 15, Chaussee de Wavre, Bruxelles.

ELECTRIC LIGHT FOR MINES.

This is not the best season of the year for attracting the attention of the general public to the subject of explosions in mines. The atmospheric condition is equable and comparatively safe; there are no startling announcements of colliery explosions, with their ghastly tale of figures, which at another time of the year become almost monotonous with daily repetition. But, for that very reason, this is the time for making an effort to prevent their recurrence, to try experiments which may now be conducted with safety, but which, later on, it would be impossible, or at all events dangerous, to attempt. On these grounds, therefore, we would earnestly re-invite the attention, not of the public so much as of electricians, to this most important subject—a subject which will assuredly bring both fame and profit to him who may be fortunate enough to dispose of it satisfactorily.

We say re-invite their attention, for there was no lack of it when popular favour first warmly espoused the electric light. Its applicability to the lighting of coal mines was at once fully appreciated by those who were scientifically engaged in the work, and we heard of several isolated attempts to establish its practicability. From time to time we have notified the introduction of the light into a mine here and there, but, for some cause yet to be explained, the experiments have not been so numerous as we had hoped and expected. Some discouragement probably arose from the supposed necessity for using currents of such a strength and character as to be of themselves dangerous. The successful application of perfectly safe currents above ground for lighting purposes has removed this hindrance to the lighting of underground spaces, and we see no present reason why a fresh effort should not now be made on the part of electric light promoters to include the proprietors of mines among their best customers.

The immediate cause of the terrible catastrophes to which all toilers in mines—especially, of course, in coal mines—are periodically exposed is usually a subject of conjecture, the only witnesses who could afford positive testimony having been launched beyond the reach of all questioning. But there is little doubt that failure of the safety lamp, or negligence in its use, is at the bottom of most of the accidents traceable to the explosion of fire damp. Davy's invention was, undoubtedly, one of the most beneficent contributions to the welfare of mankind that science has ever conferred; but in an indirect way it has not improbably led to greater carelessness in the matter of ventilation, and therefore to greater risks in the employment of any sort of light where carburetted hydrogen is apt to collect. It would, we suppose, be almost treason to hint at the possibility of the lamp itself, under certain conditions, being capable of igniting an explosive gas; but so many accidents do occur notwithstanding the obligatory use of the safety lamp that we are unable always to attribute them to the culpable negligence of the men most profoundly interested in using it with care. The lamp is not considered quite safe, we believe, when an explosive mixture passes through it with great rapidity—a condition of things that may be brought about at any moment, for example, by the accidental rupture of a partition dividing two adjoining galleries the atmospheres of which are at different temperatures. One of its merits is that it is extinguished when an atmosphere is entered which would be fatal to the bearer, thus giving him timely warning of his danger. But here the temptation arises to obtain a light even at the risk of an explosion, for though the platinum wire which encoils the flame continues to give off a faint glow after the lamp itself is put out, the man is soon left in darkness. He wants to resume work with natural, and sometimes with incautious, haste, the consequences of which are only too often disastrous.

Now, what is wanted under these circumstances is an adequate illumination of the mine in a manner that the carrying of lamps would be rendered superfluous, and explosions from causes directly or indirectly attributable to their use impossible. The electric light, it seems to us, is just the thing to supply this very grave defect. Its fitness is indeed so obvious that we need not enlarge upon it here. With incandescent lamps duly protected, wires properly encased, and

Digitized by Google

currents powerless to do mischief, there is no reason why the shafts and galleries of every mine should not be as well lighted as any factory or workshop after dark. Some experiments would, of course, have to be made, owing to the novel conditions under which installations of this kind must be carried out; but the nature of the difficulties to be overcome is pretty well understood, and this, we say, is the time of the year when the attempt to overcome them can best be made.

The question of expense ought not, in a case of this sort, to stand in the way of so great an improvement. There is here no competition with gas to be considered; the electric light would present itself on its own merits without a rival, and those merits are of the highest possible kind where the hardships of human labour and the danger to human life can be so greatly mitigated by its means. And this observation applies to all classes of mines, whether collieries or not, for undoubtedly miners in general would pursue their callings under greatly improved conditions, and their output would consequently be proportionally augmented if they were allowed the inestimable privilege of working in an atmosphere thoroughly well lighted and at the same time thoroughly safe.

CORRESPONDENCE.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I think it is evident from the diagram and letter of "T.L.P." in your paper last week that he has made three errors in testing his lightning conductors.

1. He should have used the same lengths or resistances for his two No. 16 B.W.G. leading wires, or have noted the difference in their resistance before soldering them to his lightning conductor (C) and main water earth (M.W.), and connecting them respectively to his Wheatstone bridge and resistance-box (R). Any difference in the resistance of these two leading wires must appear as a + or — error in his results unless allowed for or cancelled.

2. He says he tested with three Leclanché cells. Now, it is well known that such cells polarise or "run down" very quickly when in circuit with such low resistances as he had to deal with, and thereby tend to give unstable results. He will find good Daniell cells of low resistance, having well amalgamated zinc plates placed in a saturated solution of sulphate of zinc, and clean copper plates in a saturated solution of sulphate of copper, with thin porous diaphragms between the zinc and copper, much better for his purpose; but even with these he should not keep his battery on for a longer time than is just necessary to get a balance.

3. Owing to his employing for the one earth a *leaden* pipe and for the other a *cast-iron* one, there must have been present a current from the one to the other, which current would affect his galvanometer when it was brought into circuit, and act with or against his battery current according to circumstances. With such an arrangement of earths it is necessary to balance to the earth current (or false zero as it is sometimes termed), and not to the zero of galvanometer, and to take the mean of readings with + and — or alternate currents before perfectly uniform results can be obtained, in precisely the same way as that of testing a submarine cable for copper resistance.

If "T.L.P." has had the copper band from his lightning conductor fixed in the way mentioned to the cast-iron pipe (S.W.) for some time with no further precautions, and if it is in a damp or wet situation, would he kindly look at it now and say whether he observes any eating away of the cast-iron pipe near the junction. I have seen the whole of the sheathing from the heavy shore end of a submarine cable eaten away in a few months by a similar mode of attachment. Perhaps he will kindly repeat his tests, taking note of the three above-mentioned possibilities of error, and give us his results through the columns of your valuable paper.

The accidents from lightning last week have been serious and numerous, and such results as "T.L.P." has given us are valuable, more especially owing to their scarcity. I have tested several lightning conductors, using two or three different earths for the testing battery, with a view of obtaining the *absolute* resistance in ohms to earth of the lightning conductor, and not the resistance between its earth and that of any one of the battery earths, but I never got such low results as "T.L.P.'s" ·31 and ·46 ohm.—Yours, &c.,

Glasgow, 12th June, 1883. A. J.

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The remarks made by Mr. Mordey in the earlier part of his letter of last week need no answer. In the latter part he credits me with an experiment I did not perform as concerns the Schukert machine. When he added the two remaining magnets he not only doubled his lines of magnetic force, but he also (according to his theory) doubled the wires cutting those lines. Of course, when he added his two remaining magnets, he should have *kept his total magnetism constant*. I am surprised he did not obtain a much greater increase than he reports.

As in all proofs of the kind, "quantitative" proof is always open to objection; but as a qualitative proof of the true action of the Gramme ring, that of Marcel Deprez, with which I have only just become acquainted, is conclusive to the extreme. I append the translation as nearly as may be:—

"Take a ring of the Gramme type, surround it with a cylinder of iron, and put it in motion; we present then a a magnet successively outside of the cylinder of iron and inside, in the two cases induction produces itself sensibly with the same intensity; to operate with precision, account should be taken of the difference of distance. The experiment has not been pushed to this point, but such as it is there results from it that the covering of iron does not constitute a screen."

The same number of *La Lumière Electrique* (Feb. 24, 1883) contains some account of further indirectly conclusive experiments by M. J. Stefan on the "Action of Iron as a Magnetic Screen." M. Stefan's experiments also appear in the *Annalen der Physik u. Chemie* (Wiedemann's) Dec. 2, 1882.—Yours, &c., Paget Higgs.

"INFORMATION WANTED."—MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: While admitting the correctness of Mr. Sprague's remarks relative to magnets, I should like to call "Neuralgia's" attention to the medical effects of passing an electric current, continuous or intermittent, through an organ or part of the body which is a seat of disease.

Having both felt the effects of and applied to patients with very beneficial results an interrupted current of moderate intensity, I shall be pleased to furnish him with the necessary information for procuring suitable apparatus.

Though, as Mr. Sprague says, magnets "can do no work unless an external supply of energy is provided," yet when energy (electrical) from the consumption of zinc, or from mechanical force, is expended in overcoming the resistance of the tissues of the body, and stimulating nervous action both sensory and motor, it is not difficult to conceive a definite physical effect. And with those of your readers who have had some practical experience in electric lighting it will be more than a matter of conception. In these cases, as in the more common of shocks from the coils exhibited in fairs, market places, &c., the results are as likely to be injurious as beneficial.

But with coils and batteries properly and scientifically constructed to do their work, the writer has no doubts as to the immense amount of good that may be done in removing

Digitized by Google

diseases such as rheumatism, which result from an accumulation of waste products not thrown off, as in a healthy man they are, by the lungs, the kidneys, and the skin.

I fear I should be trespassing on your valuable space if I attempted to demonstrate the physiological actions above suggested.—Yours, &c.,

A. W. BENNETT,

Nottingham. Queen's Medalist, Animal Physiology.

THE PASSAGE OF ELECTRICITY THROUGH GLASS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your current volume, page 27, there is a short notice of experiments by M. Foussereau on the passage of electricity through glass. In a recent number of a contemporary of yours there was also a notice of these experiments of M. Foussereau. The two notices do not agree, but, while they do not contradict one another, they show that there is much valuable information to be obtained concerning the nature of electricity if the particulars of these experiments were published. They corroborate the accuracy of the experiments of mine which you published some time ago, whereby I proved that the theory of the Leyden jar depends on a portion of the electricity passing through the glass of the jar. I hope that you may be able to give the details of M. Foussereau's experiments.—Yours, &c., JAMES JOHNSTONE.

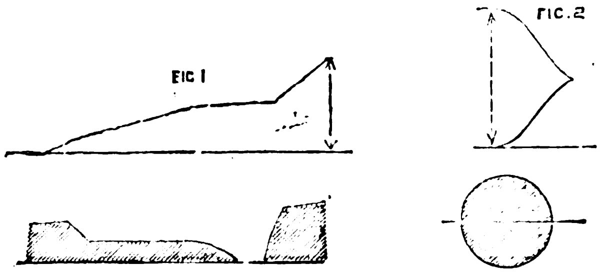
8, Dalhousie-terrace, Edinburgh. June 2, 1883.

ON METERS FOR POWER AND ELECTRICITY.*

BY MR. C. VERNON BOYS.

The subject of this evening's discourse—"Meters for Power and Electricity"—is unfortunately, from a lecturer's point of view, one of extreme difficulty, for it is impossible to fully describe any single instrument of the class without diving into technical and mathematical niceties which this audience might well consider more scientific than entertaining. If then, in my endeavour to explain these instruments and the purposes which they are intended to fulfil, in language as simple and as untechnical as possible, I am not as successful as you have a right to expect, I must ask you to lay some of the blame on my subject and not all on myself.

I shall at once explain what I mean by the term "meter," and I shall take the flow of water in a trough as an illustration of my meaning. If we hang in a trough a weighted board, then, when the water flows past it, the board will be pushed back; when the current of water is strong, the board will be pushed back a long way; when the current is less it will not be pushed so far; when the water runs the other way the board will be pushed the other way. So by observing the position of the board, we can tell how strong the current of water is at any time. Now, suppose we wish to know, not how strong the current of water is at this time or at that, but how much water altogether has passed through the trough during any time, as, for instance, one hour. Then, if we have no better instrument than the weighted board, it will be necessary to observe its position continuously to keep an exact record of the corresponding rates at which the water is passing every minute, or better every second, and to add up all the values obtained. This would, of course, be a very troublesome process. There is another kind of instrument which may be used to measure the flow of the water—a paddle-wheel or screw. When the water is flowing rapidly the wheel will turn rapidly; when slowly, the wheel will turn slowly; and when the water flows the other way, the wheel will turn the other way, so that if we observe how fast the wheel is turning we can tell how fast the water is flowing. If, now, we wish to know how much water altogether has passed through the trough, the number of turns of the wheel, which may be shown by a counter, will at once tell us. There are therefore, in the case of water, two kinds of instruments, one which measures at a time, and the other during a time. The term meter should be confined to instruments of the second class only. As with water so with electricity, there are two kinds of measuring instruments, one of which, the galvanometer, may be taken as a type, which shows by the position of a magnet how strong a current of electricity is at a time, and the other which shows how much electricity has passed during any time. Of the first, which are well understood, I shall say nothing; the second, the new electric meters and the corresponding meters for power, are what I have to speak of to-night. It is hardly necessary for me to mention the object of making electric meters. Every one who has had to pay his gas bill once a quarter probably quite appreciates what the electric meters are going to do, and why they are at the present time attracting so much attention. So soon as you have electricity laid on in your houses, as gas and water are laid on now, so soon will a meter of some sort be necessary, in order that the companies which supply the electricity may be able to make out their quarterly bills, and refer complaining customers to the faithful indications of their extravagance in the mysterious cupboard in which the motor is placed. The urgent necessity for a good meter has called such a host of inventors into the field, that a complete account of their labours is more than any one could hope to give in an hour. Since I am one of this host, I hardly like to pick out those inventions which I consider of value. I cannot describe all, I cannot act as a judge and say these only are worthy of your attention, and I do not think I should be acting fairly if I were to describe my own instruments only and ignore those of every one else. The only way I see out of the difficulty is to speak more particularly about my own work in this direction, and to speak generally on the work of others.



I must now ask you to give your attention for a few minutes to a little abstract geometry. We may represent any changing quantity, as the strength of an electrical current, by a crooked line (Fig. 1). For this purpose we must draw a straight line to represent time, and make the distance of each point of the crooked line above the straight line a measure of the strength of the current at the corresponding time. The size of the figure will then measure the quantity of electricity that has passed, for the stronger the current is the taller the figure will be, and the longer it lasts the longer the figure will be, either cause makes both the quantity of electricity and the size of the figure greater, and in the same proportion, so the one is a measure of the other. Now it is not an easy thing to measure the size of a figure, the distance round it tells nothing; there is, however, a geometrical method by which its size may be found. Draw another line, with a great steepness where the figure is tall, and with a less steepness where the height is less, and with no steepness or horizontal where the figure has no height. If this is done accurately the height to which the new line reaches will measure the size of the figure first drawn, for the taller the figure is the steeper the hill will be, the longer the figure the longer the hill; either cause makes both the size of the figure and the height of the hill greater, and, in the same proportion, so the one is a measure of the other; and so, moreover, is the height of the hill, which can be measured by scale, a measure of the quantity of electricity that has passed.

The first instrument that I made, which I have called a "cart" integrator, is a machine which, if the lower figure is traced out, will describe the upper. I will trace a circle. The instrument follows the curious bracket-shaped line that I

* Lecture delivered at the Royal Institution of Great Britain.

Digitized by Google

have made sufficiently black to be seen at a distance (Fig. 2). The height of the new line measures the size of the circle. The instrument has squared the circle. This machine is a thing of mainly theoretical interest. My only object in showing it is to explain the means by which I have developed a practical and automatic instrument, of which I shall speak presently. The guiding principle in the cart integrator is a little three-wheeled cart, whose front wheel is controlled by the machine. This, of course, is invisible at a distance, and therefore I have here a large front wheel alone. On moving this along the table any twisting of its direction instantly causes it to deviate from its straight path. Now, suppose I do not let it deviate, but compel it to go straight, then at once a great strain is put upon the table, which is urged the other way. If the table can move it will instantly do so. A table on rollers is inconvenient as an instrument, let us, therefore, turn it into a roller (Fig. 3), then on moving the wheel along it the roller will turn, and the amount by which it turns will correspond to the height of the second figure drawn by the cart integrator. If, therefore, the wheel is inclined by a magnet under the influence of an electric current, or by any other cause, the whole amount of which we wish to know, then the number of turns of the roller will tell us this amount; or to go back to our water analogy, if we had the weighted board to show current strength, and had not the paddle-wheel to show total quantity, we might use the board to incline a disc in contact with a roller, and then drag the roller steadily along by clock work. The number of turns of the roller would give the quantity of water. Instruments that will thus add up continuously indications at a time, and so find amounts during a time, are called integrators. The most important application

FIG. 3

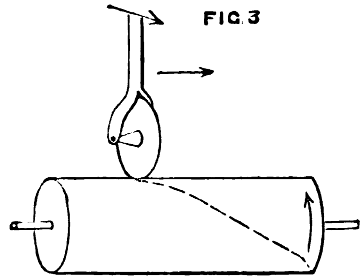


FIG. 4

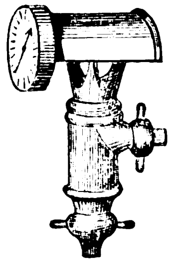


that I have made at present of the integrator described is what I have called an engine-power meter. The instrument is on the table, but as it is far too small to be seen at a distance, I have arranged a large model to illustrate its action. The object of this machine is to measure how much work an engine has done during any time, and show the r sult on a dial, so that a workman may read it off at once, without having to make any calculations (Fig. 4).

Before I can explain how work is measured, perhaps I had better say a few words about the meaning of the word "work." Work is done when pressure overcomes resistance, producing motion. Neither motion nor pressure alone is work. The two factors, pressure and motion, must occur together. The work done is found by multiplying the pressure by the distance moved. In an engine steam pushes the piston first one way, then the other, overcomes resistance, and does work. To find this we must multiply the pressure by the motion at every instant, and add all the products together. This is what the engine-power meter does, and it shows the continuously growing result on a dial. When the piston moves it drags the cylinder along; where the steam presses the wheel is inclined. Neither action alone causes the cylinder to turn, but when they occur together the cylinder turns, and the number of turns registered on a dial shows with mathematical accuracy how much work has been done.

In the steam engine work is done in an alternating manner, and it so happens that this alternating action exactly suits the integrator. Suppose, however, that the action, whatever it may be, which we wish to estimate is of a continuous kind, such, for instance, as the continuous passage of an electric current. Then, if by means of any device we can suitably incline the wheel, so long as we keep pushing the cylinder along, so long will its rotation measure and indicate the result; but there must come a time when the end of the cylinder is reached. If then we drag it back again, instead of going on adding up, it will begin to take off from the result, and the hands on the dial will go backwards, which is clearly wrong. So long as the current continues, so long must the hands on the dial turn in one direction. This effect is obtained in the instrument now on the table, the electric energy meter, in this way. Clockwork causes the cylinder to travel backwards and forwards by means of what is called a mangle motion, but instead of moving always in contact with one wheel, the cylinder goes forward in contact with one and back in contact with another on its opposite side. In this instrument the inclination of the wheels is effected by an arrangement of coils of wire, the main current passing through two fixed concentric solenoids, and a shunt current through a great length of fine wire on a movable solenoid, hanging in the space between the others. The movable portion has an equal number of turns in opposite directions, and is therefore unaffected by magnets held near it. The effect of this arrangement is that the energy of the current—that is, the quantity multiplied by the force driving it, or the electrical equivalent of mechanical power—is measured by the slope of the wheels, and the amount of work done by the current during any time, by the number of turns of the cylinner, which is registered on a dial. Professors Ayrton and Perry have devised an instrument which is intended to show the same thing. They make use of a clock, and cause it to go too fast or too slow by the action of the main on the shunt current; the amount of wrongness of the clock, and not the time shown, is said to measure the work done by the current. The method of measuring the electricity by the work it has done is one which has been proposed to enable the electrical companies to make out their bills.

The other method is to measure the amount of electricity that has passed without regard to the work done. There are three lines on which inventors have worked for this purpose. The first, which has been used in every laboratory ever since electricity has been understood, is the chemical method. When electricity passes through a salt solution it carries metal with it, and deposits it on the plate by which the electricity leaves the liquid. The amount of metal deposited is a measure of the quantity of electricity. Mr. Sprague and Mr. Edison have adopted this method; but as it is impossible to allow the whole of a strong current to pass through a liquid, the current is divided; a small proportion only is allowed to pass through. Provided that the proportion does not vary, and that the metal never has any motions on its own account, the increase in the weight of one of the metal plates measures the quantity of electricity.

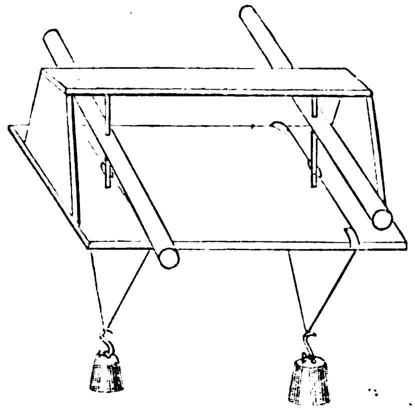
The next method depends on the use of some sort of integrating machine, and this being the most obvious method, has been attempted by a large number of inventors. Any machine of this kind is sure to go, and is sure to indicate something, which will be more nearly a measure of the electricity as the skill of the inventor is greater.

Meters for electricity of the third class are dynamical in their action, and I believe that what I have called the vibrating meter was the first of its class. It is well known that a current passing round iron makes it magnetic. The force which such a magnet exerts is greater when the current is greater, but it is not simply proportional. If the current is twice or three times as strong, the force is four times or nine times as great, or generally, the force is proportional to the square of the current. Again, when a body vibrates under the influence of a controlling force, as a pendulum under the influence of gravity, four times as much force is necessary to make it vibrate twice as fast, and nine times to make it vibrate three times as fast; or generally, the square of the number measures the force. I will illustrate this by a model. Here are two sticks nicely balanced on points, and drawn into a middle position by tapes to which weights may be hung (Fig. 5). They are identical in every respect. I will now hang a 1lb. weight to each tape, and let the pieces of wood swing. They keep time together absolutely. I will now put 2lb. on one tape. It is clear that the corresponding stick is

Digitized by Google

going faster, but certainly not twice as fast. I will now hang on 4lb. One stick is going at exactly twice the pace of the other. To make one go three times as fast it is obviously useless to put on 3lb., for it takes four to make it go twice as fast. I will hang on 9lb. One now goes exactly three times as fast as the other. I will now put 4lb. on the first, and leave the 9lb. on the second; the first goes twice while the second goes three times. If instead of a weight we use electro-magnetic force to control the vibrations of a body, then twice the current produces four times the force, four times the force produces twice the rate; three times the current produces nine times the force, nine times the force produces three times the rate, and so on; or the rate is directly proportional to the current strength. There is on the table a working meter made on this principle. I allow the current that passes through to pass also through a galvanometer of special construction, so that you can tell by the position of a spot of light on a scale the strength of the current. At the present time there is no current; the light is on the zero of the scale; the meter is at rest. I now allow a current to pass from a battery of the new Faure-Sellon-Volckmar cells which the Storage Company have kindly lent me for this occasion. The light moves through one division on the scale, and the meter has started. I will ask you to observe its rate of vibration. I will now double the current. This is indicated by the light moving to the end of the second division on the scale; the meter vibrates twice as fast. Now the current is three times as strong, now four times, and so on. You will observe that the position of the

FIG 5



spot of light and the rate of vibration always correspond. Every vibration of the meter corresponds to a definite quantity of electricity, and causes a hand on a dial to move on one step. By looking at the dial we can see how many vibrations there have been, and therefore how much electricity has passed. Just as the vibrating sticks in the model in time come to rest, so the vibrating part of the meter would in time do the same, if it were not kept going by an impulse automatically given to it when required. Also, just as the vibrating sticks can be timed to one another by sliding weights along them, so the vibrating electric meters can be regulated to one another so that all shall indicate the same value for the same current, by changing the position or weight of the bobs attached to the vibrating arm. The other meter of this class, Dr. Hopkinson's, depends on the fact that centrifugal force is proportional to the square of the angular velocity. He therefore allows a little motor to drive a shaft faster and faster, until centrifugal force overcomes electro-magnetic attraction, when the action of the motor ceases. The number of turns of the motor is a measure of the quantity of electricity that has passed.

I will now pass on to the measurement of power transmitted by belting. The transmission of power by a strap is familiar to every one in a treadle sewing machine or an ordinary lathe. The driving force depends on the difference in the tightness of the two sides of the belt, and the power transmitted is equal to this difference multiplied by the speed; a power meter must, therefore, solve this problem—it must substract the tightness of one side from the tightness of the other side, multiply the difference by the speed at every instant, and add all the products together, continuously representing the growing amount on a dial. I shall now show for the first time an instrument that I have devised, that will do all this in the simplest manner (Fig. 6). I have here two wheels connected by a driving band of india rubber, round which I have tied every few inches a piece of white silk ribbon. I shall turn one a little way, and hold the other. The driving force is indicated by a difference of stretching, the pieces of silk are much further apart on the tight side than they are on the loose. I shall now turn the handle, and cause the wheels to revolve; the motion of the band is visible to all. The india rubber is travelling faster on the tight side than on the loose side, nearly twice as fast; this must be so, for as there is less material on the tight side than on the loose, there would be a gradual accumulation of the india rubber round the driven pulley, if they travelled at the same speed; since there is no accumulation, the tight side must travel the fastest. Now it may be shown mathematically that the difference in the speeds is proportional both to the actual speed and to the driving strain; it is, therefore, a measure of the power or work being transmitted, and the difference in the distance travelled is a measure of the work done. I have here a working machine which shows directly on a dial the amount of work done; this I will show in action directly. Instead of india rubber, elastic steel is used. Since the driving pulley has the velocity of the tight side, and the driven of the loose side of the belt, the difference in the number of their turns, if they are of equal size, will measure the work. This difference I measure by differential gearing which actuates a hand on a dial. I may turn the handle as fast as I please; the index does not move, for no work is being done. I may hold the wheel, and produce a great driving strain; again the index remains at rest, for no work

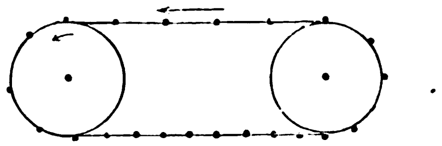


FIG. 6.

is being done. I now turn the handle quickly, and lightly touch the driven wheel with my finger. The resistance, small though it is, has to be overcome; a minute amount of work is being done, the index creeps round gently. I will now put more pressure on my finger, more work is being done, the index is moving faster; whether I increase the speed or the resistance the index turns faster; its rate of motion measures the power, and the distance it has moved, or the number of turns, measures the work done. That this is so I will show by an experiment. I will wind up in front of a scale a 7lb. weight; the hand has turned one-third round. I will now wind a 28lb. weight up the same height; the hand has turned four-thirds of a turn. There are other points of a practical nature with regard to this invention which I cannot now describe.

There is one other class of instruments which I have developed of which time will let me say very little. The object of this class of instruments is to divide the speed with which two registrations are being effected, and continuously record the quotient. In the instrument on the table two iron cones are caused to rotate in time with the registrations; a magnetised steel reel hangs on below. This reel turns about, and runs up or down the cones until it finds a place at which it can roll at ease. Its position at once indicates the ratio of the speeds which will be efficiency, horse-power per hour, or one thing in terms of another. Just as the integrators are derived from the steering of an ordinary bicycle, so this instrument is derived from the double steering of the "Otto" bicycle. Though I am afraid that I have not succeeded in the short time at my disposal in making clear all the points on which I have touched, yet I hope that I have done something to remove the very prevalent opinion that meters for power and electricity do not exist.

switch, as shown in Fig. 17. In the case where there is no exchange wire, or the private lines *may* be put through to exchange, the switch S and bell A will not be required, and the

to Unhook or Replace the Telephone, the Local Circuit of the Transmitter being Closed and Broken by these Movements alone, will be seen from Fig. 18. which shows the

Digitized by Google

necessary apparatus and connections. C is a spring switch, B a case containing a polarised relay and induction coil. The action is as follows:—When the telephone is taken off the hook, a momentary current is sent to line, entering B at terminal 3, passing through secondary of coil, coils *t t* of polarised relay (which causes the arm A to move over and come in contact with S), terminal 4 to earth.

The primary circuit is as follows:—From the carbon of local cell to T, terminal 2, microphone contact S A, now closed, primary coil, terminal 1, and zinc of local cell. The transmitter is then in action.

When the telephone is hung up a momentary current is sent to line in the reverse directon to that first mentioned. This causes the arm A to leave the contact S, and thus break the primary circuit. No current is passing to line from the switch battery except during the time the telephone is being unhooked or hung up.

To Join Three Stations on One Line.—All the switch bells should be made to make and break contact, as shown at Fig. 19. The stations at each end of the line are connected as usual. The line is then looped into the centre station, one end being connected to terminal L, and the other end being connected to terminal E, instead of that terminal being connected to earth as usual. The zinc of battery must be connected to terminal E. Three stations may also be connected on what is practically one line by the use of the switch as shown in Figs. 14, 15, and 16 (page 64).

Battery Commutator.—This is the same form of switch as illustrated in Figs. 10, 11, 12 (page 64). The sketch, Fig. 20, explains itself.

The Telephone.—The form of Professor Bell's instrument used in this country is shown in section in Fig. 21. A is the magnet, TT terminals, B coil of fine wire, C pole piece, D diaphragm, E ebonite case, F screw cap of same. The action of the telephone depends on the well-known principle that when a coil of insulated wire is placed on the end of a permanent magnet, or its soft iron pole piece, any movement to or from the pole piece of an iron armature induces a current in the coil of wire. The armature is represented by the diaphragm D. To enable the telephone to reproduce speech an undulatory current must be employed, *i.e.*, a current that, so to speak, waves above and below a certain strength. This current may be either constant in one direction or alternating. The number of times per second that the diaphragm of a telephone vibrates determines the pitch, the loudness of the sounds produced depends on the extent of the vibrations. If the diaphragm be spoken against it vibrates in unison with the voice, and as the diaphragm is the armature of the magnet, corresponding undulating currents are generated in the coil of wire surrounding the magnet. When the instrument is connected up for use, the currents pass to line and into the coil of the receiving telephone, causing the magnetism of its magnet to be strengthened and weakened. The diaphragm approaches and recedes from the pole piece in unison with the diaphragm of the sending telephone, and this vibration acting on the air conveys to the ear a repetition of the words spoken into the sending telephone, but very much reduced in loudness. In practice, however, the sounds received are found to be too weak for practical purposes, and until battery transmitters came into use the application of the telephone was very limited. It is now, therefore, the universal practice to employ battery transmitters, which will be referred to further on.

The Adjustment of the Telephone.—In some of those first made the magnet was cemented into the ebonite cases by means of paraffin wax, pieces of which constantly chipped off, and got between the diaphragm and the pole piece. No allowance being made for their presence, the articulation was much deadened, or stopped altogether. Sometimes, again, the paraffin would be melted by heat, and run down between the diaphragm and pole piece, cementing the whole together. Some precaution was necessary to prevent these faults, and the writer advises all inspectors who have to deal with such instruments to provide discs of tissue paper an eighth of an inch larger in diameter than the opening of the bell in the telephone, with a hole in the centre three-quarters of an inch in diameter. Have them well gummed all over, and keep a supply at hand. To apply these discs, wet the gum on one of them, and stick it on the coil as central as possible. Press the outside edge down into the bell, so that it will not touch the diaphragm at any part, replace the diaphragm and cap, and the fault referred to will not occur in future. If it is found necessary to remove the paper at any time another can readily be put on. The manufacturers have, however, discontinued the use of wax, and a hard varnish is used instead, so that in the newer instruments these faults are not so liable to occur. Foreign particles are sometimes in the improved instrument to be found in the case, but the use of the gummed tissue paper provides the remedy. Be sure that the coil is firm upon the pole piece, or it may at times slide up and touch the diaphragm. The diaphragm D should be as close to the piece C as possible without touching, and the screw cap should be screwed down lightly. If the diaphragm is tightly fixed the articulation is much impaired. The diaphragm should not be buckled or bent in any way, or it is useless trying to get good results. If it cannot be readily set flat change it at once.

Although the coil wire in the telephone is not liable to become broken, it may become so at times, owing to electrical discharges from the line passing through it when in circuit; it is therefore advisable, when tracing a fault, to test it with a battery. If in good order a sharp click will be heard when contact is made; if none is heard, the instrument had better be returned for repairs. This test should be made with wire direct into the telephone terminals, and not through the cord, as the fault may exist in that and not in the telephone. The cord may afterwards be tested with the instrument attached if the telephone is found O K.

(TO BE CONTINUED.)

PROFESSOR FLEEMING JENKIN ON ELECTRIC LIGHTING.

The following is the first portion of a report by Professor F. Jenkin, F.R.S., on behalf of certain local authorities in respect of provisional orders promoted by companies. It will be seen that many of Professor Jenkin's suggestions are similar to the modifications adopted by the Board of Trade. This report was made at the end of January last:—

I.—Efficiency of Supply.

(*a*.) *Continuity of Supply.*—The undertakers do not propose to give a *continuous* supply—they reserve the right of interrupting the supply of electricity (s. 21 *f*) during certain intervals in the daytime. These intervals are, it is said, not on the whole to exceed *two hours* per diem.

It is obvious that the undertakers mean to avail themselves of this privilege, for they propose that the interruptions shall occur at *stated hours*, but they stipulate that this interruption may be allowed occasionally at other hours. They further propose to cut off the electricity during the greater part of each Sunday.

Long before the 21 years have expired for which the order will remain in force I am of opinion that in whole quarters of the town electrical lighting will have entirely superseded gas in private houses—that houses will have been built in which no gas pipe will be found. I am further of opinion that the supply of electricity for motors will have become an essential part of the economy of the city. Under these circumstances the power to cut off the supply of electricity habitually for two hours, and occasionally with no warning and no penalty, would inflict intolerable inconvenience and loss. The interruption might even be dangerous to life. Under these circumstances I am of opinion that no provisional order should be sanctioned which does not provide for a continuous supply of electricity, which shall not be interrupted except in case of *force majeure*. I see no reasons for permitting interruption in the case of electricity which do not apply with equal force to gas and water. I would from the outset oppose any attempt on the part of the companies to force consumers to adopt expensive and troublesome storage batteries to play the part which cisterns play in the case of water. Interruptions for the purpose of testing are quite unnecessary until there is some *primâ facie* ground for believing that defects exist; then notice of the intention to test should be served on every customer, and the hour chosen when least inconvenience would be caused.

As a possible concession I would perhaps allow the undertakers to interrupt the supply for a short period daily, during perhaps the first three months or six months of their working, until they had gained experience, but as a permanent arrangement discontinuous supply would be intolerable. Electricity is not a luxury or a toy; the supply will henceforth be a necessity of life.

(*b*.) *Constancy of Supply.*—The constancy of supply to a given consumer depends on the maintenance of what in the Provisional Order is termed the *pressure* in the mains. In order that the consumer may have a constant supply the pressure in the mains near his house must be kept constant. This is not sufficiently provided for in the draft order.

A standard pressure (21 *b*.) and (21 *e*) is to be fixed by the undertakers and sanctioned by the Board of Trade; then it is provided that the difference of potential (21 *c*.) shall not at any point vary more than 10 per cent. from the corresponding standard pressure. It is, however, expressly stipulated that the "standard pressure may be different for different points of the main, and for different hours during the period of supply."

Digitized by Google

As worded I consider that this allows the undertakers at certain points of the town to have normally a pressure 10 per cent. in excess of the prescribed standard, and at other points a pressure normally 10 per cent. below the prescribed standard. I think this an excessive allowance, and I would reduce the whole variation to 10 per cent., *i.e.*, to 5 per cent. on each side of the standard pressure.

But two distinct questions appear here to be mixed—the variation between different points of the mains and the variation at any one given point. These two questions are closely connected, but are not identical. A variation of pressure at any one spot of 10 per cent. from the standard pressure would be intolerable. It would cause continual failure of the incandescent lamps by allowing them to fall to a dull red; or, on the other hand, by raising them to excessive incandescence, it might break and extinguish them suddenly. Even 5 per cent. on each side of the standard would prove inconvenient, and the commercial exigencies of satisfying their customers will lead the companies to give much greater steadiness than this, but I would not render a a variation within this moderate range penal.

There will be no great hardship in allowing a difference of pressure in different parts of the town of 10 per cent., provided at each point the fluctuations throughout the day did not exceed 5 per cent. The two ideas may, perhaps, be kept distinct by calling the one place-variations and the other time-variations. The place-variations might be 10 per cent., but the time-variations should not exceed 5 per cent. I must, however, observe that I see great difficulty (with any method of supply at present known) in so arranging the times that a place-variation of 10 per cent. might occur without *ipso facto* rendering an occasional time-variation of the same amount possible; it may, therefore, be most prudent to demand the 5 per cent. variation in both respects. It should also be noted that all the regulations concerning standard pressure are applicable only to the *parallel arc system* (11 *a. b. & c.*).

Provision must be made that even within the 5 per cent. limit the pressure be not allowed to vary rapidly or oscillate up and down, otherwise a very painful effect will be produced on the eyes. The frequent waxing and waning of the light, consequent on a change of pressure, may be produced by the unsteady running of the engine or dynamo.

The regulation of constant standard pressure approximately equal throughout the main is quite inapplicable to the "Series System" (11 *d.*). For this system a completely distinct set of regulations are required; the pressure is necessarily different at every spot. This system can only be used for arc lights, and is unsuited for domestic purposes. The regulation necessary to ensure constancy in a series system might run as follows:—When the series system is adopted, the undertakers shall state to the consumer the current in amperes which they consider necessary for the purpose indicated by the consumer. They shall also inform the local authority of the number of amperes which they intend to supply through the given circuit; after this they shall be bound, unless relieved by special agreement, to supply a current through this circuit at all hours of the day and night which does not vary by 5 per cent. from the "stated current."

Should they or the consumer desire a change in the stated current, this should only be made after giving notice to the local authority, and if it should appear that the consumer had been misled by the undertakers and so had erected unsuitable apparatus inside his premises, the expense, or some part of the expense, of any alteration should fall on the undertakers. The essential difference between the two systems is that in the one case the pressure must be constant, in the other case the current.

When alternating currents are adopted, the number of alternations per minute should be maintained constant. This number might be fixed differently on different mains, but once fixed, the undertakers should not alter it by more than 5 per cent. from the stated number. If, however, the consumers could show that they suffered by any defect or excess in the number of alternations, then the local authority should have the right to call upon the undertakers to make the necessary change in their apparatus.

(*c.*) *Necessity for Revision.*—It is not possible at this moment to foresee what pressure in the mains will be most advantageous for all purposes, present and future. It is most probable that hereafter separate mains at different pressures will be required. It is almost certain that changes will be required in the pressure first adopted. Nevertheless, these changes when made will involve alterations which may be great and expensive in the internal fittings for private and public purposes. The undertakers require the leave of the Board of Trade before changing the pressure. I see no provision made by which the local authority may call on the undertakers to make the change, but I think they should have this power, also the power of calling on the undertakers to lay down new mains at a different pressure on showing that a reasonable probability of profit exists, and perhaps subject to the approval of the Board of Trade. I also think that a provision should be inserted providing for the compensation of the consumer in case the pressure is changed by the desire of the undertakers in such a way as to throw fresh outlay on the consumer.

The powers taken under (11) seem to me reasonable, but the company may begin by selecting one of these systems, which, as knowledge advances, may be found less advantageous than some other system, either described in (11) or as yet unknown. Provision seems to me to be necessary for facilitating a change either on the demand of the undertakers or of the local authority without damaging the consumer (*vide* 31). Provisions similar to those suggested above seem to me to meet the case, but it might be reasonable to give the local authority the power to demand a change, in case some other system was in other towns proved to be more efficient, even though the change might not be immediately profitable to the undertakers. In a seven years' license I would not insist on these points, but it is impossible to foresee the developments of electrical science and apparatus during the next twenty-one years.

It will be seen hereafter that I do not contemplate in all cases forbidding the use of what are called "earth returns" (11), but I think that the local authority should have the power of forbidding earth returns if from any cause these should prove inconvenient. I apprehend that the Board of Trade already has the power of forbidding these if they should hereafter be proved to be dangerous in any unforeseen way; but, without being dangerous, they may prove highly inconvenient, possibly causing the decay of water or gas pipes, or interfering with the telephone system, or with some new electrical system as yet unthought of. The powers given to the local authority to call upon the company to make extensions or changes should be subject to some appeal. The Board of Trade seems to be contemplated as the natural court of appeal, but I may venture to suggest that they will only be able to decide these scientific questions on the advice of skilled experts, and I would ask you to consider whether in some cases procedure might not be simplified if the President of the Institution of Telegraph Engineers, or some person appointed by him, were at once named as the arbitrator, to decide whether certain demands were reasonable. It is for the legal advisers of the local authorities to devise how a clause should be framed giving the towns a power of revising the terms granted to the undertakers, but I conceive it to be my duty to point out the many ways in which revision may become desirable.

(*d.*) *Supervision.*—Clauses 46 to 51 contain provisions allowing the Board of Trade to test the mains for insulation and conductivity. I fail to see what good result is to come of these tests. Want of conductivity and bad insulation will cause loss to the undertakers, but this very fact will ensure the employment of proper conductors and insulators. With such precautions as I elsewhere advise, no danger can arise from defective conductivity or insulation, and I should, in the interests of the local authorities, prefer that these clauses should be deleted. I fear that the approval of the Board of Trade may occasionally be used as a protection to the undertakers, to which I think they are not entitled. The lines may be well insulated and of good conductivity, and yet be wholly unsuited for the work they have to do. They may be of insufficient dimensions; they may be insufficiently protected against injury; they may be insulated with a material of good electrical properties, but bad mechanical properties, as by being too soft; they may be badly arranged in many ways, and yet when a faulty service results from these defects, the undertakers may plead that the lines were passed by the Board of Trade. If the pressure specified is maintained at the customers' poles, the local authorities have, so far as I can see, no interest in requiring either good conductivity or high insulation.

I would not delete 52, which may possibly be useful, though I should not recommend that it be largely applied. Similarly, 53 gives a useful power, 55 requires extension. The undertakers should, at the points referred to in this clause, set up three instruments—known respectively as ergmeters, ammeters, and voltmeters—measuring respectively the energy, the current, and the difference of potential. The ammeter is absolutely essential to allow the authorities to verify that the condition inserted in Sec. 62 (a) is complied with. The records should, when possible, be *continuous*, and the burden of showing that a continuous record is impossible at reasonable cost should fall on the undertakers. Copies of the record should be furnished daily to the local authorities. If it be said that these instruments are not yet perfected, it may be answered, with the utmost confidence, that if not yet perfect in all respects they will very shortly be so made as to be far more trustworthy than gas meters. The continuous record of what is happening at the source of the supply will be most valuable to the local authority as enabling them to ascertain whether any complaints as to the supply depend on causes over which the undertakers have control. They can be

Digitized by Google

sent to men of standing for their opinion in case of doubt, and do not require the appointment by the towns of electricians of equal skill with those of the undertakers—a burden from which the towns should be saved.

I would insert a fresh clause to the following effect:—The undertakers shall, at their own expense, fix at suitable points in connection with the mains, instruments capable of showing the pressure in those mains at all hours of the day and night, and such as can be read by persons of moderate skill. These instruments are called voltmeters. The places where these are fixed should be determined in concert with the local authority, and the inspector of the local authority should have access to them. The undertakers should be bound to use self-recording instruments so soon as these can be produced at a reasonable price. That this can be done is undoubted. The one point on which the local authorities may insist is that the standard pressure fixed for each main shall be maintained day and night without the 5 per cent. variation, and they may call on the undertakers to prove that this has been done. The borough engineers will be perfectly competent to examine these records.

I would further insert a clause giving each customer the right to have, on payment of a reasonable charge, one of these pieces of apparatus fixed either permanently or temporarily in connection with the poles inside his house, with the object of ascertaining whether the standard pressure is maintained for his particular supply. In connection with this point I must hereafter revert to Sec. 21 (d), which I consider objectionable.

The meters of all kinds should be subject to verification of the same kind as is now applied to gas meters.

While, however, I would relieve the local authority from all scientific supervision of the undertakers' plant, I think a clause would be most useful requiring the undertakers before executing any works to send full particulars of those works to the local authority; thus they should be required to furnish accurate maps showing the proposed and accurate position of all mains, distributing boxes, and testing boxes. They should send in drawings of all the apparatus they propose to employ except the engines, dynamos, and special appliances required on any premises where the electricity is generated. Thus the local authority should be informed of the size of every main; the mode of insulation employed; the manner of protecting the mains as by cast-iron pipes or otherwise; the form of the distributing boxes and testing boxes; the design of any pole or support visible in the public part of the town. I would not give the local authorities any veto on scientific grounds. This would shift the responsibility to the wrong persons; but, on grounds of what we in Scotland term "amenity," I would give the local authority power to object to the design of any structure visible in the public streets. And further, I would give a veto on the ground that the proposed works would interfere with some other necessary or desirable public or private works. Thus the proposed erections might interfere with tramways, gas distribution, water distribution, *fire escapes*, telephone wires and ordinary traffic. Moreover, the towns would be entitled to object if the mode employed of laying and repairing the mains was not that which would cause the least interruption to ordinary traffic. Already plans exist by which the mains can be repaired and multiplied without breaking up the street, and improved methods of doing this will undoubtedly be devised. I am not, therefore, in favour of at present defining exactly what the undertakers may or must do, but should prefer to call upon them to deposit tracings of all their working drawings, and giving the local authority power to object on the grounds above stated, subject to appeal.

In respect of apparatus employed on the undertakers' premises I would only call upon the undertakers to state the indicated horse-power which the engines were capable of exerting, to give a general description of the dynamos they employ, and to keep the local authorities informed of any material changes they make from time to time in their system. The mere necessity of making these statements will act as a useful check against abuses, even when the local authority retains no power of veto.

(*e.*) *Consumers' Right to Supply.*—The provisional order does not, in my opinion, ensure that all consumers who may reasonably demand electricity shall be supplied. In Schedule C, Section I, it is stipulated that the undertakers may charge £3 10s. per quarter for any quantity up to 100 units; this amounts to a refusal to supply small customers. In my opinion every consumer should have a right to be supplied, even if he only wants one incandescent lamp occasionally. All that the undertakers have a right to require is that the consumers should themselves pay the charges of connecting their lamps with the mains, and of the necessary meters. There is no hardship whatever in requiring them to supply small customers or persons who only occasionally use electricity. No scientific difficulty exists to justify this limitation. I will return to the point under the head of price. In Section 26, I think the distance, 50ft., too small. I see no hardship in extending this limit to 100ft., or even more, if the cost of the service line is, beyond 20ft., to fall on the consumer.

If, hereafter, mains of different pressures are employed in the neighbourhood of his premises, the consumer should have the right to choose from which main he will be supplied. If in some mains an alternating current is used, in others a constant current, the consumer should have the right of choice; further, if he desires to be supplied from all the mains in his neighbourhood separately, he should have the right to these several supplies which he may desire for several reasons—as to avoid all risk of interruption, or to use the electricity for different purposes.

(*f.*) *Size of Mains.*—The size of the mains should be such that for the contemplated supply the current through the main should not exceed a certain number of amperes. This in my opinion might be fixed at about 500 amperes per square inch, but I should not object to 800, although this would, I think, be less advantageous to the undertakers. It is, I think, important to require that the undertakers (in giving such notice of their intentions as I have recommended under head *d*) state what maximum supply they contemplate giving, and at the same time to specify the size of the main, and, subject to such possible revision as is alluded to under head *c*, I would fix at once the quantity of copper to be employed. This will prevent the undertakers from laying down inefficient mains in the first instance, and is a wholly distinct question from that of safety. It will be found that, for reasons of safety, the undertakers are prepared to submit to a limitation of current through any main, and there is, therefore, no hardship in requiring them at once to fix the quantity of metal they will use to convey a given current. The limit for safety is hereinafter fixed at 1,200 amperes. A further security that mains of sufficient size are put down would be given by a clause requiring that no change inside premises supplied should cause a sensible variation of pressure at the poles; this is not sufficiently provided for by the 5 per cent. limit named under head *b*. It would be intolerable if turning on or off lamps on the premises caused a charge of 10 per cent. (*i.e.* from lowest to highest limit) in the available pressure.

(*g.*) *Retail Dealers.*—Difficulty may hereafter arise from what I may term retail dealers in electricity. The undertakers cannot object if certain shops bottle up a certain quantity of electricity, as in storage batteries, and in carts send it elsewhere to be employed in any way—but the following case is worthy of consideration, and I am not sure that it is provided for in the order. A retail dealer may find it worth his while to extend his service lines to several neighbouring houses which are not entitled to a supply direct from the mains—he complies with all the conditions laid down, gives notice of the quantity he requires, and pays for it. Is he to be at liberty to supply his neighbours in this way, and, if so, to what extent? He might supply whole streets and be subject to no regulations.

(*h*). *Notice to be Given by Customers; Advice to be Given by Undertakers.*—I think it very objectionable that (28) the intending customer should be required to state the *maximum current* with which he desires to be supplied. He will usually not have the knowledge enabling him to make this statement. He may fairly be called upon to state all the uses he proposes to make of electricity simultaneously; then the responsibility of advising him what current he requires should fall on the undertakers, who should also give him all necessary particulars as to the service wires he requires to bring the electricity to his poles. Then the customer may fairly be required not to exceed the maximum of which he has given notice; but, *per contra*, if the advice given him proves wrong, the expense of any alteration in the service wires should fall on the undertakers in part or wholly. Proper clauses framed with this object would obviate the necessity for Clause 21 (*d.*), which in any case seems to me objectionable. The undertakers should be the scientific advisers of the customers up to the poles, and I should be prepared to trust to the ordinary commercial motives as a safeguard against any excessive demands by the undertakers for wires of great size. They must be responsible for everything up to the poles, and it is therefore reasonable to leave the design as well as the execution in their hands. If the customer *prefers* to state the maximum quantity he requires rather than state the uses, he should be at liberty to do so. In all cases where the undertakers supply the apparatus they should be bound to state the conditions for their effective working in respect of current and pressure, and their responsibility would then extend to the interior of the house.

I may here draw your attention to the fact that the 50 amperes per house mentioned in (29) will be frequently exceeded. I do not, however, see that Clause 29 is objectionable. 50 amperes will suffice for about 35 Swan lamps, and this number will often be exceeded.

Digitized by Google

(*i*). *Penal Clauses.*—I express no opinion as to the sufficiency of the penalties in 57, 58, and 59, but Clause 60 is surely objectionable. Even in the present state of electrical science, a failure to comply with the terms of the order recurring frequently in one day would show great ignorance or carelessness. There will be no more difficulty in supplying electricity than in supplying gas or water. I think the clause should be struck out.

Further penalties are required, or further definition of what a failure to supply means. I would suggest that the accidental extinction of more than one light simultaneously in a house should, of itself, be held to show that the undertakers were in default and should entail a small penalty.

Secondly, that the simultaneous accidental extinction of all the lights, or a considerable portion of the lights on a given main, should subject the undertakers to a penalty increasing with the duration of the time which the extinction lasts.

I would also provide a penalty for the proved unsteadiness of the lights, even though the waxing and waning remained within such limits as are consistent with the permitted five per cent. variation of pressure If the undertakers carry their 10 per cent. limit the waxing and waning might be quite intolerable within this margin. In what is written above "extinction of lights" should be held to include the cessation of any action to which the electricity is applied.

A remedy should, I think, be provided for the following injury to which the customers will be liable. It is possible that, by some accidental variation of pressure in the mains, the lamps throughout a whole establishment, or indeed throughout whole streets, may be simultaneously broken. I mean that the carbon filaments of the incandescent lamps may all be burnt up in one minute by a change from which the safety fuse does not protect the customer. Other injuries may be done to other apparatus. A simple remedy for this wrong should be provided.

II.—Price.

(*j.*) *Cost of Incandescent Lighting.*—The price which the undertakers propose to fix as the maximum which they are entitled to charge will make incandescent domestic lighting about twice as costly as lighting by gas at 4s. per 1,000 cubic feet. The calculation is made as follows:—A burner using five cubic feet per hour and giving what is called twenty candle light would consume gas worth at the above rate $\frac{24}{100}$ths of a penny per hour. One incandescent Swan lamp to give the same lights uses 1·4 ampere with a pressure of 50 volts. The unit by which the charge is to be fixed (Schedule C) is 1,000 volt-amperes; the above quantity in volt-amperes is the product of 50 × 1·4 divided by 1,000, or $\frac{7}{100}$ths of a unit. Since each unit is to cost 7d., this makes the cost of the Swan lamp $\frac{49}{100}$ths of a penny per hour, or about double that of gas.

I am not prepared to say that in the present condition of electric lighting this rate of charge as a maximum is unreasonable. It is not impossible that consumers may find that they can supply themselves with electricity by means of a gas engine at a cheaper rate, but if so the undertakers will certainly lower their prices.

(*k.*) *Cost of Arc Lighting.*—The cost of arc lighting would per candle-power be much smaller than that reckoned above for incandescent lighting, but comparisons with gas are for this system in my opinion misleading. The result produced is so extremely different that the two systems can hardly be compared. Since, however, for incandescent lighting, the price proposed is not unreasonable, I am prepared to admit that it is reasonable for arc lighting.

(*l.*) *Cost of Motive Power.*—The price named will be prohibitory as regards motive power. The number of volt-amperes divided by 746 gives the horse-power represented by that supply; or, in other words, 746 volt-amperes would be required per hour to give one horse-power if perfect efficiency were secured. This perfect efficiency is even theoretically unattainable; but it is probable that a high degree of efficiency will soon be attained. Even, however, allowing 90 per cent. of efficiency, 830 volt-amperes would be required per hour per horse-power, or $\frac{83}{100}$ths of the unit in the provisional order. The cost of this would be 5·8d. per hour. A gas engine will supply the power for less than one penny per hour. In all these calculations I have taken the cost of electricity at 7d. per unit, because, as I shall presently show, I think the other figure given, of £3 10s. per quarter, inadmissible. It might, perhaps, be easy to induce the undertakers to insert a clause specially contemplating the revision of price in respect of motive power by presenting to them the following consideration. If they are allowed, as I propose, to employ distributing mains at high pressure, they will be able to give electricity much more economically by these mains than they can by the low-pressure mains employed for electric domestic lighting. I would therefore suggest that a clause be inserted providing that if the employment of high pressure be now or hereafter authorised, the price charged for electricity from a high-pressure main shall be substantially lowered, and fixed by arbitration, so as to give a reasonable profit.

(*m.*) *Mode of Charging.*—The mode of charging proposed (Schedule C), viz., a fixed sum per unit of 1,000 volt-amperes is in itself reasonable. It is equivalent to charging a sum proportional to the horse-power required to produce the supply given. When the pressure is approximately constant, this is a fair basis. As already stated, when the pressure varies, the mains to give a certain power vary in dimension, becoming smaller as the pressure increases; therefore, it is reasonable that the price should diminish when the pressure increases, but with a fixed low-standard pressure for the ordinary distributing mains, I have no objection to make either to Section 1 or Section 2 of Schedule C. Both sections provide for charging in substantially the same way, and the liberty which the undertakers reserve to themselves of measuring the number of units supplied in one of two ways is a freedom which they may properly be allowed, seeing that we do not yet know whether meters for measuring current or for measuring energy can be most cheaply made, most easily kept in order, or regulated most accurately. I have myself no doubt that cheap and accurate meters of all kinds can be produced. The mode of charge suggested in Section 3 (Schedule C) would also be unobjectionable if the consumer were the person entitled to elect that he should be charged in this way. As it stands, however, the proposal is wholly inadmissible, and is, perhaps, the strangest clause in the whole order. The consumer is supposed to state the maximum quantity he will require per hour under Section 28. I have already said that this burden should not fall on the consumer, but whether named by him or by the undertakers there is no doubt that before the service wires are fixed a maximum quantity for a given supply must in some way be settled. Let us then suppose that this maximum quantity is settled; it may be a maximum which the consumer may only require once a year, as when he gives a ball, or more probably once a month or so. This maximum may on these occasions be tenfold what he will use on an average, and yet the company, under Section 3, would have the right to elect to charge him as if he were using the maximum quantity for every hour during which any electricity was being supplied. The absurdity does not even stop here. Let us suppose that the consumer abandons the idea of asking for a maximum supply beyond his average wants (although this would be a hardship); nevertheless, he must fix his maximum as sufficient for the largest number of lamps which he will use at once on any one evening. The proposal, as I read it, is to charge him for every minute during which even one lamp is lighted at the rate calculated from that which the undertakers are entitled to charge when the full supply is on. In other words, if the consumer asks for 50 lamps, and is charged 7d. per unit for electricity when 50 lamps are burning, he will be charged 29s. 2d. per unit when he is only burning one lamp. The proposal is so monstrous that I have endeavoured to find some other meaning than that which I attach to this clause, but I fail to find an alternative construction. I imagine this proposal must have originated in some doubt whether good meters could be produced, whereas there would be no doubt that the simple flow of the electricity into the house would drive a clock registering the number of hours during which electricity was turned on. For certain purposes such a mode of charging would be quite fair, but to give the undertakers the power to adopt it whenever they please, and to base their charge on the maximum supply at full prices, is quite impossible. Section 4 is open to similar objections.

(*n.*) *Suggestions as to Price.*—Some revision of the price charged should be arranged. It is impossible to foresee what will be a fair charge twenty-one years hence. A limitation of dividends might be considered, but seems to me false in principle, since it tends to discourage further improvements when the maximum has once been reached. A most favoured nation clause occurs to me as possible of the following kind—that the undertakers shall be bound to afford all facilities and modes of supply which shall from time to time be proved to be remunerative in any town of Great Britain unless cause can be shown why these modes of supply are inapplicable to Great Yarmouth or the special town in question. Moreover, that the rates charged for all modes of supply shall not exceed those charged for similar supplies of electricity in any other town of Great Britain by more than 20 per cent., unless special cause can be shown for the excess in the town in question, to the satisfaction of arbitrators. The 20 per cent. of excess would prevent the question of rates being mooted in a vexatious and unnecessary manner; and some such clause seems necessary to prevent companies which are burdened with heavy patent royalties from acquiring a disadvantageous monopoly. Many companies are weighted by agreements taxing them heavily for the benefit of certain patentees. So long as the instruments protected by the patents really give a better supply than others which

Digitized by Google

are supplied at a cheaper rate, this burden is perfectly legitimate and advantageous to the consumer; but it is at least conceivable that hereafter apparatus less heavily burdened by royalties may give a still better supply, and it would then be greatly to the disadvantage of the towns that they should be in the hands of persons bound to use the more expensive apparatus. Under these conceivable circumstances, the royalties should be paid by a diminution in the dividends, and not by the consumers, who have no interest in the employment of one machine rather than another. At the same time, it is obvious that few companies for the supply of electric lighting have been formed, or would be formed, except on the basis of some special patent, and there would be no objection to this if such a most favoured nation clause as I have suggested were incorporated in all provisional orders. If some device of this kind be not invented it will become the interest of all towns to hold back and delay the introduction of electric lighting; for those which come last will be best served—obtaining the benefit of the experience derived on the towns first supplied.

(*o.*) *Price of Fittings.*—I think it would be desirable that the undertakers should be bound to supply fittings of all descriptions such as they approve of at prices to be fixed from time to time by arbitration, so as to allow of a good trade profit. If this be not done, the undertakers, in answer to complaints, will often be able to lay the blame on the internal fittings. While consumers should be at liberty to buy these fittings anywhere and of any make, the company should be bound to supply those which it thinks best. Patterns of these fittings, with the prices fixed, should be deposited with the local authorities.

When lamps or other forms of apparatus are supplied to customers by the undertakers, means should be provided by which the customer can have, at a cheap rate, tests made of their efficiency.

Should the undertakers strongly object to supplying very small customers—although this seems to me impolitic on their part—a sliding scale of prices might be agreed on by which a somewhat larger rate might be charged when the average consumpton fell below a certain amount. As another protection to the undertakers, it might be reasonable to allow them a greater latitude as regards the perfection of their service, their mode of charging, and their prices during the first three years after beginning their supply.

ON INCANDESCENT LIGHTING.*

BY WILLIAM SIEMENS.

(CONTINUED FROM PAGE 96.)

Of two equally large installations of incandescent lights—the one carried out with the Swan and the other with the Edison lamp—the former would accordingly (as the Swan requires about double the current of Edison) necessitate about four times as expensive a "lead." This circumstance, so unfavourable for the Swan lamp, is of more consequence the larger the installation and the farther the current is produced from where it is used, so that central installations with Swan lamps can only be carried out with more or less difficulty.

One can, it is true, obviate the disadvantage arising from the costliness of the conductor with lamps of low E.M.F., by taking refuge in certain combinations of the parallel and "series" systems of circuiting the lamps. The number of these combinations is unlimited. In the Swan lamps we frequently find that two or more lamps are put "in series," and these pairs amongst themselves are circuited "in parallel;" or that the installation consists of two or three great groups circuited "in series," each of which consists of an equal number of lamps circuited "in parallel." The first arrangement possesses the disadvantage that simultaneously with the one lamp the entire pair become extinguished. Under the second arrangement the going out of one lamp is not at once accompanied by that of another. It must be noticed, however, that if any branch circuit is broken the current through the other branch is increased, exposing the lamps therein to danger.

For certain installations the group arrangement will be acceptable (as, for instance, at the Savoy Theatre). In cases, however, where the lamps are required to burn singly, independently of each other, and where it is desirable to be able to put in and out of current single lamps, or a larger number of the lamps in the same circuit, the single multiple arc system is preferable.

I will now speak of lamps of different intensity, but which burn in the same circuit in greater detail.

I assume similarity of materials, molecular structure, and temperature. Each square centimetre of surface will have a fixed radiating capacity, whether the surface belongs to a thin or thick carbon, or whether a lamp of high or low tension is concerned. A unit surface would correspond to a certain wax candle, and hence the illuminating power of the lamp may be given in candles.

How shall the lamp be constructed so that lamps of different size may be put into the same circuit? The answer depends upon several conditions. Are the lamps to be in multiple arc or in series, are they adjusted for a constant difference of potential or for a constant strength of current—*i.e.*, is E or C to be maintained constant? As we have assumed similar materials and temperature, if l represents the length, d the diameter of the carbon taken as round, and R_s the specific resistance of the same : $E \,.\, C = l \,.\, d$.

Let us first consider the case where the lamps are circuited in series, and the current constant:

$$C^2 R d = l\,d; \quad \frac{C^2 R_s\, l}{d^2} = l\,d; \quad C^2 R_s = \text{const.} = d^3; \text{ or } d = \text{const.}$$

The condition, therefore, for lamps of different illuminating power burning in series in the same circuit is, assuming similarity of temperature, that the diameter of the carbon be in all lamps the same. Lamps of different luminosity can thus be distinguished by their length. Practically, of course, this circumstance is of no importance, as for a large number of lamps in series the E.M.F. required would become too considerable, and for each lamp, taking it as of 10 ordinary candle-power, certainly not less than from 30 to 40 volts would be required, assuming the conductor not to be thicker than that of the Swan lamp, and to be kept within the limits of temperature.

The usual mode is for lamps to be connected parallel. On this account the different lamps must require the same E.M.F.

That is, $E\,C = l \,.\, d$ or $\dfrac{\frac{E^2}{W_s}\,.\,l}{d^2} = l.d$ or $\dfrac{E^2}{W_s} = \text{const.} = \dfrac{l^2}{d}$. Let l_1 and d^1 be the dimensions of a given lamp, and l^1 and d^1 those of one required to use similar E.M.F. and temperature, then $\dfrac{l^1}{d^1} = \dfrac{l_1{}^2}{d_1} = \text{const.} : l^1 \,.\, d^1 = m \,.\, l_1 \,.\, d_1$, in which m shows the proportion between the two surfaces or candle-powers. The two unknown (quantities) l^1 and d^1 can be fixed therefrom.

The existence of lamps of different luminosities in the same circuit with constant difference of potential is dependent upon $\dfrac{l_2}{d} = \text{const.}$ Lamps are not only distinguished by their length of carbon, but in a higher degree by its diameter.

The E.M.F. chosen for lighting purposes will be as high as possible. Assuming identical materials and identical temperature, a certain surface corresponds to 10 candle-power (a less luminary would hardly be required for domestic purposes). If the carbon is of the smallest diameter possible (*i.e.*, so that it meets the requirement of sufficient stability), the length is made such as to give the radiating surface required for 10 candles. A unit size is thus determined by the illuminating power which one desires to give to the smallest lamp of the system, and upon fineness of the carbon without endangering durability.

Considered from a purely theoretical point of view, one might choose an E.M.F. of an unlimited value, and thus realise the dictum that the power of a light-installation is independent of the distance of the source of the current (as Deprez has in a similar manner formulated for the effective power of the transmission of energy).

The condition, therefore, that the effective power of a transmission of power remains constant under variation of its distance is $\dfrac{E^2}{W} = \text{const.}$ The same holds good of the effective power of a light installation. In it $\dfrac{E^2}{W}$ represents the power consumed in the lamp, which corresponds to a certain illuminating power. In the same measure as the distance or the resistance of the conductor is increased must also the resistance of the carbon be increased, so that the proportion between the work lost in the conductor and the total work remains the same. As the illuminating power of the lamps has not to be altered, the required difference of potential is shown by the relation $\dfrac{E^2}{W} =$ constant. In like manner is the new strength of current determined by $C^2 W = \text{constant}$. The larger W and E are made, so much the thinner is the carbon filament, and as the uttermost limit in this respect is soon reached, in the impossibility of making the carbon filament indefinitely thin lies the practical limitation of the universal dictum—that the effective power is independent of the distance.

Whilst in the case of incandescent lamps the limitations of this dictum lie in the small variations W is susceptible of, in the

* Translated from the *Electrotechnische Zeitschrift*, March, 1883.

Digitized by Google

transmission of power the obstacle is in E, or in the difficulty of insulating the wires.

With the present materials for carbons, and in the actual position of the manufacture, I do not believe that more than from 100 to 110 volts can be employed even for 10 candle-power lamps. The E.M.F. at which the incandescent lights of the firm of Siemens and Halske are adjusted is 105 volts. The close agreement of our lamps with the Edison lamps in respect to E.M.F. is more than accidental. It is, as I have explained, founded on the nature of things. It must here be freely acknowledged that in the beginning of the era of the incandescent light, when Edison constructed his first lamp, he recognised the suitability to the purpose of the highest possible E.M.F.

The firm of Siemens and Halske produce lamps of three different illuminating powers, of 10, 16, and 25 candles.

The E.M.F. required is 105 volts.

Candle-power. *	Diameter.	Length.	Section (at area).	Surface.
10	0·15	110	0·017	50
16	0·20	125	0·031	75
25	0·27	145	0·056	120

It is an actual æsthetical necessity that these lamps, particularly when present in the same room, should burn with uniform tone and tint, and this, provided the carbon material is the same, is secured by uniform temperature. In this case the superfines of the different carbons must be (stand) as the corresponding illuminating powers, which is approximately the case in the above-mentioned lamps.

(TO BE CONTINUED.)

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.†

(CONTINUED FROM PAGE 92.)

Between 1705 and 1711, Hauksbee made many valuable and interesting observations, of which we must content ourselves with a brief *résumé*, referring our readers for fuller accounts to the original papers in the *Philosophical Transactions*, or to Priestley's excellent "History and Present State of Electricity," pp. 15-23, 5th Ed. In 1705, he showed that light could be produced by passing common air through mercury, contained in a well-exhausted glass receiver. The air, rushing through the mercury, blew it against the sides of the glass, and made it appear like a body of fire, consisting of an abundance of glowing globules. In repeating this experiment with about three pounds of mercury, and making it break into a shower, by dashing it against the crown of another glass vessel, flashes resembling lightning, of a very pale colour, and distinguishable from the rest of the produced light, were thrown off from the crown of the glass in all directions.‡ Hauksbee likewise showed that considerable light may be produced by agitating mercury in a partially exhausted tube; and that even in the open air abundance of flashes of light are discoverable by shaking quicksilver in any glass vessel.

In a subsequent series of experiments on the light produced by the attrition of bodies *in vacuo*, he showed that glass, when thus excited, emitted light in as strange a form as lightning, particularly, when he used a rubber that had been previously drenched in spirit of wine. In all these experiments Hauksbee had no notion of the electrical origin of the light, and in saying that it resembled lightning he was only using a simile, without any suspicion of a closer connection.

Like Sir Isaac Newton, Hauksbee employed a glass globe machine, as he thought that this material was capable of more powerful effects. When exhausted of air, and turned briskly, the application of his hand would produce a strong light on the inside; and, by re-admitting the air, light appeared on the outside also. By bringing an exhausted globe near to an excited one, he found that a light was produced in the former, which soon disappeared; but which immediately reappeared, with great beauty, on again exciting the globe.

The following experiment must at that time, and indeed long after, have been considered one of great singularity. Having coated one half of the inside of a glass globe with sealing-wax, which in some places was an eighth of an inch thick, and, therefore, quite opaque, he exhausted it and put it in motion. On applying his hand, for the purpose of excitation, its outline soon became distinctly visible on the concave surface of the wax, which thus appeared to be transparent, although before excitation it would only just allow the flame of a lighted candle to be seen through it in the dark. The same result was obtained when pitch, or common brimstone, was substituted for the sealing-wax.

Besides light and crackling noises, Hauksbee also noticed that an electrified body was able to produce a sense of pain (the electric shock) in the hand, or face, that touched it—an observation which is also claimed for his friend, Dr. Wall.

This latter philosopher is, however, best known as being the first to suspect the identity of lightning and electricity. The happy thought was suggested to him, as he tells us in a paper read before the Royal Society in 1708, by the sparks and crackling sounds produced by the friction of a large stick of amber against a woollen cloth. "Upon drawing," he says, "the piece of amber swiftly through the woollen cloth, and squeezing it pretty hard with my hand, a prodigous number of little cracklings were heard, every one of which produced a little flash of light; but when the amber was drawn gently and slightly through the cloth, it produced a light, but no crackling. By holding a finger at a little distance from the amber, a crackling is produced, with a great flash of light succeeding it; and what is very surprising, on its eruption, it strikes the finger very sensibly, wheresoever applied, with a push or puff like wind. The crackling is full as loud as that of charcoal on fire; nay, five or six cracklings, or more, according to the quickness of placing the finger, have been produced from one single friction, light always succeeding each of them. Now I doubt not but on using a longer and larger piece of amber, both the cracklings and light would be much greater. This light and crackling seem in some degree to represent thunder and lightning" (Hutton's *Phil. Trans. Abridged*, Vol. 5, p. 409).

So far, experimenters had worked without any system, and without in the least comprehending the principles on which the effects they produced depended. Highly important, therefore, as were all their observations, the true foundations of electricity as a science cannot be said to have been laid until Stephen Gray, a pensioner of the Charter-house, London, gave to the world that justly celebrated series of experiments which, begun in 1720, only ended with his last breath in 1736.* As from this point the domain widens, we will confine ourselves in the rest of this chapter to noticing only such discoveries of Gray and succeeding philosophers as bear intimately on our subject.

In February, 1729, Gray discovered the principle of electric conduction and insulation, and in doing so might almost be said to have stumbled across electric telegraphy, of which it is the very *alpha* and *omega*. This important discovery was made in the following manner:—Wishing to excite in metals, as had already been done in glass, resin, &c., the power of attraction and repulsion, he tried various methods, such as rubbing, heating, and hammering; but all to no end. At last an idea occurred to him that, as a glass tube, when rubbed in the dark, communicated its light freely to bodies, so it might communicate a power of attraction, which, at this time, was considered the only absolute proof of the presence of electricity. In order to test this he took a glass tube, 3ft. 5in. long and 1 1·5in. diameter, and filled up the ends with pieces of cork to keep out the dust when the tube was not in use. His first experiment was to ascertain if there was any difference in its power of attraction when the tube was stopped at both ends by the corks, and when left entirely open; but he could perceive no sensible difference. Then holding a feather over against the end of the tube, he found it would fly to the cork, being attracted by it as readily as by the tube itself. He concluded from this that the electric virtue, conferred on the tube by friction, passed spontaneously to the cork.

It then occurred to him† to inquire whether this transmission

* These are German candles, and should be converted into English by multiplying by 1·237, and the numbers become respectively 12·37, 19·79, and 30·92.

† The author reserves all rights of translation.

‡ Electric light *in vacuo* was first observed by Picard in 1675. While carrying a barometer from the Observatory to Porte St. Michel in Paris, he observed light in the vacuous portion. Sebastien and Cassini observed it afterwards in other barometers. John Bernouilli, in 1700, devised a "mercurial phosphorus," by shaking mercury in a tube which had been exhausted by an air pump. This was handed to the King of Prussia, —Frederick I.—who awarded it a medal, of forty ducats' value. The great mathematician wrote a poem in honour of the occasion. (Tyndall's "Notes on Electricity.")

* This remarkable man was (so to speak) dying when his last experiments were made, and, unable to write himself, he dictated an account of them to Dr. Mortimer, the secretary of the Royal Society, the day before his death.—*See Philosophical Transactions*, vol. 39, p. 400, 1735-36, or Hutton's *Abridgement*, Vol. 8, p. 110.

† We follow in this and the next three paragraphs Lardner's "Manual of Electricity, Magnetism," &c., Vol. I., pp. 8-9. See also Priestley's "Hist. Elec." pp. 24-39.

Digitized by Google

of electricity would be made to other substances besides cork. With this view he obtained a deal rod about 4in. in length, to one end of which he attached an ivory ball, and inserted the other in the cork, by which the glass tube was stopped. On exciting the tube, he found that the ivory ball attracted and repelled the feather even more vigorously than the cork. He then tried longer rods of deal; next rods of brass and iron wire, with like results. He then attached to one end of the tube a piece of common packthread, and suspended from its lower end the ivory ball and various other bodies, all of which he found capable of acquiring the electric state when the tube was excited. Experiments of this kind were made from the balconies of his house and other elevated stations.

With a true philosophic spirit, he now determined to inquire what circumstances attending the *manner* of experimenting produced any real effect upon the results; and, first, whether the *position* or *direction* of the rods, wires, or cords, by which the electricity was transmitted from the excited tube, affected the phenomena. For this purpose he extended a piece of packthread in a horizental direction, supporting it at different points by other pieces of similar cord, which were attached to nails driven into a wooden beam, and which were, therefore, in a vertical position. To one end of the horizontal cord he attached the ivory ball, and to the other he tied the end of the glass tube. On exciting the tube he found that no electricity was transmitted to the ball, a circumstance which he rightly ascribed to its escape by the vertical cords, the nails supporting them, and the wooden beam.

Soon after this (June 30, 1729), Gray was engaged in repeating his experiments at the house of Mr. Wheeler, who was afterwards associated with him in these investigations, when that gentleman suggested that threads of silk should be used to support the horizontal line of cord, instead of pieces of packthread. It does not appear that this suggestion of Wheeler proceeded from any knowledge, or suspicion, of the electric properties of silk; and still less does it appear that Gray was acquainted with them; for, in assenting to the proposition of his friend, he observed, that "silk might do better than packthread on account of its smallness, as less of the virtue would probably pass off by it than by the thickness of the hempen line which had been previously used."

They accordingly (July 2, 1729) extended a packthread through a distance of about eighty feet in an horizontal direction, supporting it by threads of silk. To one end they attached the ivory ball, and to the other the glass tube. When the latter was excited, the ball immediately became electric, as was manifested by its attracting metallic leaf held near it. Next day, they extended their experiments to lines of packthread still longer, when the silk threads used for its support were found to be too weak, and were broken. Being under the erroneous impression that the escape of the electricity was prevented by the fineness of the silk, they now substituted for it thin brass wire, which they expected, being still finer than the silk, would more effectually intercept the electricity; and which, from its nature, would have all the necessary strength. The experiment, however, completely failed. No electricity was conveyed to the ivory ball, the whole having escaped by the brass wire, notwithstanding its fineness. They now saw that the silk threads intercepted the electricity, because they were *silk*, and not because they were fine.

Having thus accidentally discovered the property of insulation, they proceeded to investigate its generalisation, and found that it was enjoyed by resin, hair, glass, and some other substances.

In fact, it soon became apparent that, in this respect, all matter may be said to belong to one of two classes, the one like the packthread and brass wire, favouring the dissipation, or carrying away, of the electric power, and the other like the silk and glass opposing it.*

Armed with this knowledge, Gray and Wheeler, in July, 1729, had the great satisfaction of being able to transmit the electric power through as much as 765ft. of packthread, supported by loops of silk, and in August, 1730, through 886ft. of wire. It is curious to observe that in these experiments, as, indeed, in all others on electrical conduction, we have all the essentials—crude, of course—of a perfect telegraph, the insulated line, the source of electricity in the rubbed glass, the indicating instrument in the down feather, and the earth, or return circuit, the function of which, however, was not then suspected.

* Soon after this, in August, 1729, Gray discovered that when the electrified tube was brought near to any part of a *non-electric*, or conducting body, without touching it, the part most remote from the tube became electrified. He thus fell upon the fact, which afterwards led to the principle of induction. The science, however, was not yet ripe for that great discovery, and Gray, like Otto Guericke before him, and Wilson and Canton after him, continued to apply the principles of induction without the most remote suspicion of the rich mine whose treasures lay beneath his feet, and which it was one of the glories of Franklin to bring to light.

While Gray and Wheeler were pursuing their investigations in England, Dufay, of the Academy of Sciences, and Intendant of the Royal Botanic Gardens, was actively engaged in Paris, in a similar manner. The researches of this philosopher, so celebrated as the originator* of the double-fluid theory of electricity, embraced the period between 1733 and 1737. He added largely to the class of bodies, called *electrics*, by showing that all substances, except metals, and bodies in the soft or liquid state, might be made electric, by first heating them, and then rubbing them on any kind of cloth; and as regards even these exceptions, he showed that they, and, generally, *all* bodies, solid and liquid, could be electrified, if only the precaution were taken of first placing them on glass stands.

In repeating Gray's experiments with the packthread, he perceived that they succeeded better after wetting the line, and, with the aid of this fact, he was able to transmit the electric power along a cord of nearly 1,300ft., which he supported at intervals on glass tubes.

NOTES.

TELEPHONY IN DUBLIN.—We understand that the exchange system in Dublin is to be open day and night.

APPOINTMENT.—Mr. P. A. M'Carthy, telegraphist at Dublin, has been appointed to the postmastership of Bandon.

THE FISHERIES EXHIBITION.—It is, we believe, intended to issue invitations to view the electric lighting arrangements at the exhibition.

CHINA.—The Eastern Extension Telegraph Company and the Great Northern Telegraph Company notify the opening for traffic of a new station at Foochow.

TELEPHONIC COMMUNICATION IN BELGIUM.—The Belgian Government, by a decree of June 11th, is authorised to let by tender all the telephonic lines in the kingdom.

UNIVERSITY COLLEGE, LONDON.—The annual *soirée* of the professors was given on Tuesday night, when the visitors were able to visit the lecture rooms, theatres, museums, &c.

PHOTOMETRY.—A new form of photometer was described at the Sheffield meeting of the Gas Institute, by Mr. A. J. Vernon Harcourt, M.A., F.R.S. We hope to be able to find space for this paper in our next issue.

CHANGE OF ADDRESS.—The registered office of the Indian and Oriental Electrical Storage and Works Company will, in future, be 19, Great Winchester-street, London, E.C. Mr. H. C. Heywood is the secretary.

PERSONAL.—M. Marcel Deprez, the author of "The Experiments on the Transmission of Force to a Distance," has offered himself as a candidate for the place in the Academy of Sciences, vacated by the death of M. Bresse, in the Section of Mechanics.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of the West India and Panama Telegraph Company for the half month ended the 15th inst. are £2,540, as compared with £2,544 in the corresponding period of 1882.

THE EDISON CENTRAL STATION, NEW YORK.—The company is at present lighting 429 houses wired for 10,268 lamps from this station. The lighting commenced on September 4, and has been continued without a hitch ever since. New connections are being made daily.

CALEDONIAN CENTRAL STATION HOTEL, GLASGOW.—The laundry, cellars, and engine rooms of this hotel have been fitted up with Swan lamps, and the question of lighting up the whole of the premises by means of the electric light is, we understand, under consideration.

LONDON-PLATINO BRAZILIAN TELEGRAPH COMPANY.—The revenue of the London-Platino Brazilian Telegraph Company for the month of March is estimated at £2,404 (Western Brazilian portion £1,678, land lines £726), as against £2,603 for the corresponding period of 1882.

MUNICIPAL AND SANITARY ENGINEERS.—The annual summer meeting of the Association of Municipal and Sanitary Engineers will be held at Oxford on the 28th and 29th of June. The first paper is one by Mr. Killingworth Hedges, on "The Supply of Electricity by Local Authorities."

THE SUNDERLAND CATASTROPHE.—We hear of at least one child being rescued from the crush in a dying state, and restored to animation by means of electricity. Dr. Abrath, of the Sunderland Hospital for Foreign Seamen, had the gratification of being the successful operator in this case.

EDISON LAMPS.—To the 31st of May, 1883, no less than 334 Edison isolated plants, aggregating 65,145 incandescent lamps, were in operation in various parts of the world. Central stations are not included in this list. The Edison Company states that there has never been a fire or injury in connection with any of its plant.

CHANGE OF NAME.—In pursuance of a special resolution passed at an extraordinary general meeting held on the 28th November, 1882, and subsequently confirmed at an extraordinary general meeting held on the 19th December, 1882, the name of the Anglo-Austrian Brush Electrical Company has been changed to the International Electric Company. Mr. Frank Schloesser is acting as secretary.

TELEPHONES IN MINES.—It is stated that the Belgian company Société Cockerell is employing Bell telephones as a means for communication in their mines. The apparatus at the surface is placed in a convenient position, the connecting wires insulated with gutta percha, and the underground apparatus encased to preserve it from damp. The system has been worked since the beginning of April with great success.

TELEPHONE WORK FOR LADIES. — *Cassell's Magazine* for the current month contains a letter addressed to the publishers from Miss Merlin, lady superintendent of the United Telephone Company, in which she states that one hundred ladies are now employed by that company, nine of the exchange offices being under their care. She speaks in high terms both of the employment itself and of the manner in which the ladies have discharged their duties.

GREENWICH OBSERVATORY.—The report of the Astronomer Royal at the annual visitations states that there has been considerable magnetic activity during the year, the month of November, which was characterised by the appearance of a very large sun spot, being particularly disturbed with remarkable magnetic storms on November 17, 19, and 20, and many interesting cases of lesser disturbance. The magnetic disturbances on October 2 and November 17 were accompanied by brilliant auroras.

THE "ORONTES."—We understand that the Admiralty have arranged with the Swan United Company for the work of lighting by means of incandescent lamps H.M.S. troopship "Orontes," now lying at Chatham. The motor will be one of Gwynne's direct acting engines, driving a Siemens continuous current machine. There will be about 380 lamps used, exclusive of cargo lamps, and will include lamps of 12, 20, and 50 candle-power. These lamps all require the same E.M.F., and are therefore interchangeable.

SLEEPING WITH THE HEAD NORTH.—The following amusing paragraph is going the round of the papers. We should be glad to have some information about these "recent discoveries":—"Recent discoveries in electrical science tell us that the flow of the electric current in the northern hemisphere is more rapidly northward during the night than at other times. If this be so, considering the high electrical condition often experienced by a great many, sleeping with the head due north (or a point west of north), in the flow of this current, would seem likely to be more conducive to perfect rest."

AMERICAN LITERARY IDEAS.—Not long since we felt bound to call attention to the fact that a Belgian paper made free use of our columns without acknowledgment, and

Digitized by Google

thought from a remark then made that our American friends would take a hint. A New York paper, the *Electrical Review*, in its issue of June 7, has an article, entitled, "A History of Electric Telegraphy to the Year 1837," by J. J. Fahie. It may happen that our contemporary intends to reprint the whole of Mr. Fahie's articles, and we have only to modestly complain that no mention is made of *The Electrician* in the reprint.

INFORMATION WANTED.—A correspondent sends us a copy of a letter received from a tea plantation in India. The writer of the letter requests his agent to obtain for him an incandescent lamp, &c., as advertised in a paper which has a large colonial circulation. The lamp is worked by a battery, which is to last for 2,000 hours; and the correspondent writes, "as we only use lamps about three or four hours a day, the apparatus would last for 1½ or two years." The reference is to a Mr. D'Or's light and power battery, and to a No. 1 lamp. A little information about this lamp and battery would be useful. Can any reader supply it?

EARTH CURRENTS.—Professor Lenz is about to organise, with the aid of the Russian Geographical Society, a series of observations on terrestrial currents along four lines of Russian telegraphs—Moscow to Hazan and to Kharkoff, and Tiflis to Rostoff and Baku. The necessary instruments are ordered, and the observations will begin as soon as these are ready. These observations were highly recommended, as is known, by the International Polar Committee at its Hamburg meeting, in connection with the magnetic observations of the circumpolar stations, as well as by the Electrical Congress at Paris. Germany has already begun these observations, whilst Austria, Sweden, and Finland are about to start them.

THE THICKNESS OF PLATES IN SECONDARY BATTERIES.—Mr. J. T. Sprague, in an article to a contemporary, says:—"The thickness of the lead must be sufficient to bear its own weight and the strains put upon it after use; the peroxide plate should, therefore, be about double as thick as the other; in large batteries lead 1 millimetre thick is used, which is ·03937in., or about 24 sheets to the inch. One square foot of lead 1in. thick weighs 59·1lb., therefore this would be about 2¼lb. lead. The smaller cells are made of lead little thicker than that prepared for damp walls, which is about 4 to 5 ounces per foot. For ordinary purposes it is probable that sheets of 1½lb. and 1lb. would be most advantageous, with the formation carried so far as to convert ½lb. of the lead to peroxide on the one plate."

ELECTRICAL UNITS.—The following handy table is taken from a lecture by Professor Barker:—

Name.	Unit of	Value in absolute electro-magnetic units.
Coulomb...	Quantity......	10^{-1} or one tenth
Volt	E.M.F.	10^{8} „ one hundred million
Ohm	Resistance ...	10^{9} „ one thousand million
Ampere ...	Current	10^{-1} „ one tenth
Farad	Capacity......	10^{-9} „ one thousand millionth

Watt (ampere volt) rate of work....................	10^{7} (or ten million) ergs.
Horse-power ditto	746 x 10^{7} (or 7460 million) ergs.
Joule.....................heat	0·238 water-gram-degree cent.

ELECTRIC LIGHTING PROVISIONAL ORDERS CONFIRMATION BILLS.—During last week, four additional Bills (Nos. 4 to 7) for confirming Provisional Orders made by the Board of Trade under the Electric Lighting Act, 1882, were introduced, read the first time, and referred to the Examiners. Bill No. 4 related to Barton, Eccles, Winton, and Monton, Carlisle, Croydon, Luton, Margate, Nelson, Rochester, Scarborough, and Sudbury; No. 5, to Bermondsey, Clerkenwell, Hampstead, Holborn, Hornsey, St. George's-in-the-East, St. Giles's, St. James's, St. Martin's, London, St. Luke's, and Wandsworth; No. 6, to Limehouse, Poplar, Richmond (Surrey), Rotherhithe, St. Giles's, St. Olave's, St. Saviour's (Southwark), Shoreditch, and Wednesbury and Darlaston; and No. 7, to Barnes and Mortlake, Hackney, Islington, St. Pancras, and Whitechapel.

LEGAL.—In the Chancery Division of the High Court of Justice, on the 15th June, before Vice-Chancellor Bacon, the case of the United Telephone Company *v.* London Globe Telegraph and Maintenance Company was brought on. Mr. Aston, Q.C., and Mr. Moulton applied to restrain the defendant company from using the Hunnings transmitter, or any carbon telephone transmitters or other instruments being an infringement of the plantiffs' patent as amended by their disclaimer. Mr. Hemming, Q.C., and Mr. Goodeve, for the company, undertook not to use or sell (as to Wells's instruments sent to use in this country) any Hunnings instruments not protected by the *fiat* of the Attorney-General until trial or further order, and thereupon Vice-Chancellor Bacon ordered the motion to stand over to the hearing, and intimated that he would do all that was in his power to expedite the trial.

LIGHTHOUSE ILLUMINANTS.—Baron H. De Worms asked the President of the Board of Trade in the House of Commons on Monday last whether he would explain why, in the letter of Mr. Vernon Harcourt, gas referee to the Board of Trade (printed at page 29 of the parliamentary papers recently issued on the subject of lighthouse illuminants), there were stars signifying omissions; whether those omissions referred to the fact that Sir James Douglass had sold his lighthouse patents to a company for a very large sum of money, and also contained an opinion by Mr. Vernon Harcourt adverse to the merits of the Douglass burner; and whether he would have any objection to print the letter in full.—Mr. Chamberlain was understood to say, in reply, that the particular document referred to by the hon. gentleman was distinctly stated in the parliamentary papers to be an enclosure from the Board of Trade to the Trinity House. It was referred to in that letter as extracts from a communication from Mr. Vernon Harcourt, and it was printed in the papers precisely in the way he had stated. There would be no objection to let the hon. member see the letter in full.

RESISTANCE OF AN EARTH.—An abstract in the *Society of Telegraph Engineers' Journal* of a paper by M. F. Gattinger, says:—"The author is of an opinion that the present method, by using only one comparative measurement, is insufficient, and may lead to error, as, for example, in measuring the earth of a lightning conductor; and he proposes an improved method. Suppose the resistance of the earth, x, is to be determined, two other earths, y and z, are made, which may be of high resistance, so that iron waterpipes and such like can be used. As a rule, the resistances of the copper wire conductors may be neglected, but for very exact measures it should be taken into account. First, the resistance of the circuit containing the two earths x and y is determined—suppose it to be A. Then find the resistances, B, C, of the two circuits x and z, y and z. From the three equations, $x + y = A, x + z = B, y + z = C$, we have $x = \frac{A + B - C}{2}$; or, in words, add the resistances of the two circuits x and y and x and z, and subtract from the sum the resistance of y

Digitized by Google

and z, the remainder divided by 2 is the resistance of the earth, x."

Imitation Telegrams.—In the House of Commons on Monday, Mr. Long asked the Postmaster-General whether his attention had been called to the practice, recently adopted by certain persons, of advertising by means of announcements printed in form, and enclosed in envelopes precisely similar to those used by the Post Office Telegraph Department, which communications had been delivered by hand to householders in London in large numbers, and had caused considerable inconvenience; and, if so, whether any means existed, or could be devised, to prevent the use of such colourable imitations of telegrams. Mr. Fawcett, in reply, said:—"My attention was recently called to an advertisement of the kind described by the hon. member, and I may say that on my pointing out to the person responsible for its issue how objectionable such a form of advertisement was, he expressed his deep regret, and promised that he would never issue such an advertisement again. Whenever anything of the kind has been brought under the notice of the Department, and this has not often occurred, a remonstrance has always had the effect of stopping it." Mr. Augustus Harris, the delinquent in this case, writes to the papers to say that he had discontinued this kind of advertisement several days before Mr. Fawcett's communication reached him.

The Lighting of the Strand District.—Mr. Francis R. Reeves, secretary and general manager of the Jablochkoff Electric Light and Power Company, writes:—"With reference to the advertisement of the Swan United Electric Light Company announcing that the Board of Trade have granted to them a provisional order, under the Electric Lighting Act, for the Strand district, permit me, in justice to this company, to state that there is a condition attached to this provisional order that it is to be null and void if, within six months of the confirmation by Parliament of such order, a license be granted to us for the same district, and as such license has been agreed to by the Strand District Board of Works, with whom we are acting in perfect harmony, there is no likelihood of the Swan provisional order ever coming into effect. I may add that so determined are the Strand District Board to carry out their contract with this company that they have decided to oppose in Parliament the proposals of the Board of Trade." The above has appeared in some of our daily contemporaries. This letter involves some considerations with which the general public is, we should say, unacquainted. It is a fact that before applying for provisional orders the large electric light companies agreed as to the districts for which they should apply; and was it not agreed that the Swan Company should have the Strand district? This is but one of a number of questions we should like to see answered.

Thunderstorms.—A violent thunderstorm passed over Kendal and neighbourhood on Friday afternoon, 15th inst., during which the electric fluid struck a mill used in the manufacture of gunpowder, at Basingill, about four miles from South Kendal. The works belong to Messrs. Wakefield and Co., Gatebeck. The gunpowder exploded with great force, and the mill was completely destroyed. The only man working in the building at the time was terribly injured. On the same day at Birch Hey, near Bury, a farmer, named John Haslam, was struck by lightning in a field and instantaneously killed. In Leicester the chimney of a house in Hastings-street was struck and destroyed, but no injury done to the inmates. At Birstall, however, a cow was killed and many trees badly splintered. On the day following the Old Hall at Lumley was struck by lightning, which did considerable damage to the pictures, looking glasses, and windows. Four men, two women, and a lad are said to have been knocked down, but they appear to have suffered no serious injury. At Cairnbrook, four boys standing inside a stable were stunned and violently thrown to the ground, one of them being rendered unconscious for some time, the others suffering paralysis temporarily in their arms and legs. It was subsequently discovered that a yew tree fifty yards distant from the stable had been struck by lightning, and that marks resembling the foliage of the yew tree were imprinted on the bodies of the lads. On Sunday afternoon lightning struck the roofs of several houses in Christchurch, and set fire to the post office, destroying the telegraph apparatus. Painswick Church, near Stroud, was struck on the same afternoon, twenty feet of the spire falling through the roof. A similar accident occurred to the church at Llandinabo, Herefordshire, just after evensong, five children, who were remaining for shelter, being injured, besides considerable damage done to the structure.

The Far West.—A correspondent sends us a copy of the *Fort Wayne Gazette* of June 3, containing a report of a game of base ball by the electric light. The report reads:—"Last night was the occurrence of the long looked-for event that was to make Fort Wayne historic and cause her name to be mentioned wherever civilisation extended. Base ball is the American national game, but it was reserved for this city to be the first in the world to play it at night, and by the rays of an artificial sun. The Jenney Electric Light Company had surrounded League Park with seventeen lights of 4,000 candle-power each, an amount of light equal to 4,857 ordinary gas burners. Reflectors were arranged behind a portion of the lights so as to throw their rays up in the air, that the sky-scraping flies might be seen, while the rest illuminated the diamond. The degree of illumination was such that the game was played well, although an alarming number of strikes were called by Umpire Morrissey. It was also noticed that when the players looked directly toward one of their lamps they often had to shade their eyes with their hats. The audience in attendance was a very large one and although the turnstile registered 1,675 admissions there were at least 2,000 people present; dead-heads and those who crawled over the fence were fully 400 more. The scene when the game was in progress was a brilliant and novel one. The grand stand, crowded to overflowing, was as light as midday, and the elegant toilettes of the ladies showed to as good advantage as if in the full glare of the ball room, and in fact better, for the electric light shows colours the same as sunlight. All around the park was the thick outer darkness, but within was apparently a charmed enclosure where the sun had focused its rays while the rest of the world lay in darkness. In brilliancy and splendour the spectacle was a great success, but as a specimen of ball playing it was a very poor one." A note appended to the report says the electric light company netted over 300 dollars.

History of Modern Dynamo-Electric Machines.—An abstract of a paper by A. von Waltenhofen, in the Institute of Civil Engineers' *Transactions*, reads as follows:—"The author considers the modern dynamo-machine to be the outcome of the Pacinotti continuous induction-ring armature and Werner-Siemens principle of mutual accumulation, but the question arises as to whom the merit of combination is due, and this appears to have occurred to Professor Pfaundler, of Innspruck, in 1867. While Jacobi (1840) furnished the basis of a theory of electro-magnetic motors, Grove (1844), Joule and Scoresby (1847) and Petrie (1851) must be accredited as those who have given exact information concerning the effective work of these motors. Petrie can alone

Digitized by Google

be regarded as having given reliable data, and is also the only one who expressly states that he has taken into account that the theoretical work effected in proportion to the unit of weight of zinc depends upon the nature of the circuit in which the consumption of zinc takes place. The author considers the method of arriving at the weight of zinc consumed by weighing the plates before and after the experiment to be clumsy and inaccurate; and in his own researches has taken the measurement of the current by the tangent-galvanometer, and reckoned, from the product of the current and the known electromotive force of the battery, the effective work in kilogrammetres per second, and, by comparison of the effective work so determined with the work measured with the brake dynamometer, deduced the efficiency of the machine. Let J be the battery current in the motor when stationary, and $J - i$ the current during working of the motor, i being the counter-current induced, λ the total resistance of the circuit; then $J \lambda (J - i) = i \lambda (J - i) + (J - i)^2 \lambda$. The first term represents the current work given off from the battery when the motor is driven, or the total work D; the second, the mechanical work performed in the machine, comprised of useful work and friction; and the third, the heat-work in the circuit. The efficiency is as N : D. To find D the author employs the galvanometer to measure $J - i$, the other factor, or the electromotive force $J\lambda$, being given."

Gas v. Electricity.—The correspondents of the *Gas Journal* hailing from Scotland frequently make some pungent remarks when opportunity occurs upon the electric light, and, of course, always in favour of gas. Sometimes, however, the logical conclusion arrived at by a calm consideration of the facts is just the opposite to that intended by the writer. The following appears in the *Journal of Gas Lighting*:—"Aberdeen, Dundee, and now Perth have given ample evidence that gas is at present in greater demand than ever, despite the efforts of those who consider it a duty to humanity to vilify its use as a miserable illuminant and as a rich air polluter. Whatever influence such misstatements may have upon the popular mind at the moment of utterance, they are quickly effaced by actual facts; and, furthermore, the education which is given by gas companies and corporations to consumers as to the best methods of burning gas, the most suitable apparatus to employ, and the many purposes to which it can be applied, hitherto undreamt of by those not specially interested in the industry, have already had an awakening power, and the gas-burner quack, as well as the electric light enthusiast or greedy speculator, has a far more difficult task before him now than formerly in defrauding the public. In the city of Perth, the Gas Corporation have had their own share of troubles, arising out of the action of certain electric lighting agents who did their utmost to secure certain of the large consumers through promises of success which with existing machinery they could never perform; and not only have the commissioners succeeded in surmounting the difficulties which beset their path a year or two ago, but they have so improved and developed the works under their control that they are able to give gas to the community at such a low price as was, I daresay, thought impossible at the outset of their career." Will not the reader who looks between the lines perceive that great efforts have been made to lower the price of gas and to increase its efficiency because of the fears aroused by the advent of electricity. The users of gas in Perth have witnessed, we believe, a fall of 8d. per 1,000 feet in price within two years, and if the fear of competition with electricity had done nothing more than cause this reduction, the result would be a welcome one.

Cables.—The *Journal Télégraphique* for May 25 gives a table of the existing cables, the date when the cables were laid, their length, the number of wires per cable, the total length of wire, and the nature of the service for which the cables are used. We summarise this list:—

I.—*Cables belonging to various Governments.*

Queensland.—Advices from Brisbane, dated April 10th, described the experimental lighting of the Government Printing Offices by the Edison system under the supervision of Major Flood Page. There are wired some sixty electric lights, the majority of them of sixteen candle-power, one of thirty-two candle, and a few of eight candle-power, distributed about the building, and especially over the frames in

Digitized by Google

the composing room. The lights were suspended from the ordinary green shades. The compositors say they find the light preferable to the ordinary gas-burners, and there was a marked absence of heat. After the company, among who was the Minister for Public Works, had inspected the interesting machinery in various parts of the building, they assembled in the large composing room to hear Major Flood Page describe the merits of the Edison system of lighting. Major Flood Page said "that he wished to advance a few arguments in favour of the Edison electric light, which his audience had just had an opportunity of examining. There were two distinct kinds of lights—one the arc light, and another the incandescent, or as it was often called, the 'glow' light. The arc light was that great, big, hideous light that everybody detested, which threw great shadows that hurt the eyes, and which all the ladies said made them look pale and deathlike. But there was no lady in the room who would object to stand under the soft glowing light they had there. There was this advantage in the incandescent system—it was very simple, a servant girl could not go wrong with it. There was another point with reference to the Edison system—every light has an independent connection. If they had a hundred lamps they could put out one or fifty or ninety-nine without affecting the other ninety-nine or the fifty or the one. They lasted on an average about a thousand hours without renewing. Another point was with reference to safety. They had seen the newspaper reports of accidents that had occurred through a human body coming in contact with the electric current. There was a certain amount of motive force in some electric systems which would destroy any human being who allowed the current to pass through his body; but he had taken hold of the cable that conducted the whole of the electricity without hurt. There was no possible danger from fire in the Edison system. Of course there would be danger if the cable were badly laid, but if it were laid properly there would be none. He would just cover the globe near him with a handkerchief to prevent the glass from flying about, and break it. They would see that as soon as the light came in contact with the air it went out. Another advantage was that the electricity that was generated by the dynamo machine might also be used as a motive force. He had seen thirty sewing machines worked by it. In isolated places, such as stations in the bush, the machine would be most useful. The whole of Mr. Edison's system was laid underground." A 16 h.-p. Robey engine is used to drive the Edison dynamo at this installation.

The President of the Gas Institute on Electric Lighting.—At the twentieth annual meeting of the institute held on the 12th, 13th, and 14th inst. at the Frith College, Sheffield, the president, Mr. R. M. Paterson, among other things in his inaugural address, said:—"When, at Birmingham two years ago, it was resolved to abandon the old familiar name by which we were then known, an increase of prosperity and national importance was confidently looked for; but, however great may have been the hopes then entertained, it was not anticipated that we should so soon be universally acknowledged as the executive authority of the industry we represent. Such has been the case, through the International Electric and Gas Exhibition lately held at the Crystal Palace. When the directors of that historical building decided upon holding the exhibition, it was natural they should seek for the assistance and co-operation of those who were able to guide them; and, as you are aware, they appealed to your council to aid them in the work of the gas section. There is, in fact, no other representative body to whom they could apply; and, in the interests of proprietors of gas stock (I say it advisedly), it was fortunate our name had been altered, giving a national instead of a personal character to our organisation, and thus pointing us out to them as the legitimate authority to undertake the work. The occasion was a critical one; and if the institute had not been at hand to do that which it was of the utmost importance should be done well, it is impossible to say what disastrous consequences might have accrued to owners of gas property. It is no breach of confidence to say that had we not been appealed to, and had not the gas authorities throughout the country generously responded to the application we made to them for the necessary funds, the gas section of the exhibition would have been a dismal failure. What this would have meant at that juncture, when the advocates and admirers of electric lighting were exuberant in the recollection of their success in the same building last year, is not difficult to conceive. The value of gas property would undoubtedly have suffered, and the public would not have had an opportunity of witnessing the great capabilities of gas, both as an illuminant and as a substitute for solid fuel. The exhibition, so far as the gas section was concerned, was successful in every department: but the work specially undertaken by the committee of the Gas Institute, and notably the lighting of the nave, was eminently so. Up to the time of the exhibition, I believe the public had no conception that gas was capable of so much development; and there is substantial ground for believing that if this exhibition had preceded by a couple of years or so the Electric Exhibition of last year, ruinous launching of gas stock upon the market by timid owners would not have taken place, and the loss that was involved in the electric light scare would have been averted. Perhaps the best evidence of this is to be found in the high quotations of gas stock at the present time, compared with those of a year ago. It may be argued that other causes have operated favourably in the meantime; and that the practical failure of the electric light as a competitor with coal gas has had the most potent effect. But, from a careful review of the case, I am persuaded that the idea of the permanence and suitability of gas with which the exhibition inspired the public has been the chief cause in restoring their confidence in the value of gas property as a sound investment. If, in the end, no other good accrues from the exhibition, this one result was well worth accomplishing; and the Gas Institute may fairly congratulate itself on having been the means of doing such a truly national work in the name of Science, and on behalf of a great and important industry. Three scientific experts have been appointed to thoroughly examine and test the various gas exhibits; and, it is unnecessary for me to take up your time by discussing the subject here, tempting as it is on such an occasion as the present. But, gentlemen, these things are now matters of history. We cannot have an international exhibition on our hands every year; nor is it to be desired. Shall we, therefore, fall back at once into the simpler lines of work which have hitherto engaged our sole attention—namely, that of meeting once a year, in our associated capacity, to read and discuss papers? That meetings of this description are necessary, and that they have been productive of incalculable benefit in the development of the business with which we are connected, a review of the past history of this institute, under its old name, will speedily make patent to the most incredulous. But it will not be denied that we now hold a different position, and that a larger and more comprehensive work may not unnaturally be expected of us in the future, should occasion call for action."

SOUTH KENSINGTON EXAMINATIONS AND THE TEACHING OF PHYSICS.

BY G. W. VON TUNZELMANN, B.SC.

In teaching any branch of science there are two objects to be kept in view—the educational value of the branch selected, viz., its effect in training and developing the mind of the student, and the value of the knowledge obtained as an end in itself. The latter will probably have the first consideration in selecting a subject, but when the selection is made, whatever be the branch of science chosen, these two objects will merge into one, for a completely satisfactory grasp of the subject can only be attained by such a course of study as will most fully bring out its educational value. It is unnecessary to insist upon the great advantages conferred by scientific knowledge, as these are now universally acknowledged, and, as we are mainly concerned in the present essay with the method of teaching, we may confine our attention entirely to its educational value. It appears to me to be most necessary to press the importance of considering the subject from this point of view upon the attention both of science teachers and of students, as it is the only way of avoiding a danger inherent not only in the South Kensington examinations, but to a greater or less extent in every system of testing knowledge by examination, viz., the danger of looking upon the examination as the end, instead of merely as a test of the knowledge acquired. The author has had the evil effects of this forcibly brought under his notice in many of the papers sent in by candidates for South Kensington certificates in one or other of the branches of natural philosophy. Frequently a whole set of papers from one school will show that the teacher has endeavoured to give his pupils a competent grasp of the subject as far as they have gone, with the result, as far as the examination is concerned, that the examiner is able to assign good marks to paper after paper; and although it will generally happen that some bad papers are found in every batch, they will usually show with perfect clearness that the failure is due to the stupidity and inattention of the learner to his work. Another batch of papers sent in by pupils of a teacher whose only object has been to get a pass will show that, with perhaps a few exceptions, in the case of students who have risen above the bad instruction, and determined to learn what they could, the learners have no grasp of the subject, with the result that the only questions answered are those which have been learned by rote, while a question which requires for its answer the smallest knowledge of real principles brings out a flood of ridiculous nonsense which ensures the rejection of the paper. Such teaching as this does the greatest possible injury to the learner, who, even if he come later under the influence of a competent instructor, will have contracted evil habits of thought which he will find exceedingly difficult to get rid of, and he will very possibly have got the impression that he really has some knowledge of a subject of which he knows absolutely nothing, but which he has learned to talk about in a superficial manner. In this way a boy who would under proper instruction have become an intelligent student may be converted into a pupil of the most unsatisfactory kind that a teacher can have. Teaching of this kind, moreover, defeats its own object, for the greatest care is taken by the examiners to frame the questions in such a way as to require a real, though it may be an elementary, knowledge of the subject on the part of the candidate who desires to pass. In drawing attention to the evil effect of teaching of this kind, generally known as "cram," we do not forget that to the majority both of teachers and pupils it is a matter of considerable importance that they should pass their examination, and therefore we must expect the course of instruction to be laid down on the lines of the South Kensington syllabus. This, however, cannot be regarded as an evil, for the course of study for each of the stages has been carefully drawn up by men of large experience, who are at the same time practical teachers, and has been so arranged as, in their opinion, to give the greatest benefit to the learner. What we would, therefore, urge upon teachers and students is that, while following the course of study sketched out by the Science and Art Department, the one object in view should be the acquisition of a thoroughly sound knowledge of the subjects taken up, and if the course be worked through with this constant determination, both teacher and pupil may be confident, that in addition to acquiring useful and interesting knowledge the examination will be passed with credit to both.

We here take for granted that the student is in earnest, and the teacher competent, for it is impossible for the best teacher to obtain satisfactory results with a pupil who does not earnestly devote himself to his work, and on the other hand it would be absurd to expect a man to teach a subject of which his own knowledge is unsatisfactory. It has been pointed out again and again, and will be confirmed by every experienced teacher, that it is far more difficult to teach beginners than advanced pupils, and requires a more profound, though it may be a less extensive knowledge on the part of the teacher. We cannot expect every teacher of a science class to be versed in all the more recondite parts of his subject, but we may, and indeed must demand that his knowledge should be first hand and not second hand. If the teacher has merely got up the subject from a book, he cannot by any possibility teach it in a satisfactory manner. In the first place, he naturally gives it out as he has received it, and his pupils simply learn a number of statements, of the truth of which they can give no better proof than that the book or their teacher says so. In the second place such a teacher, never having questioned Nature for himself and pondered over her answers, will be unable to meet an unexpected difficulty, or to give his pupils the happy illustrations which will naturally occur to the teacher who is himself a student of nature. It is only when taught by one who has himself sat at Nature's feet and learned something of her ways that the study of physics can produce its proper effect in training the mind of the learner, and give him knowledge which will be useful to him, not merely to obtain a pass certificate, but as a source of future profit and delight. This bringing the mind into contact with fact is what constitutes the great value of science as a means of mental education, and for this purpose I do not think a better branch could be chosen than some portion of physics. Science is reasoned knowledge; it does not consist merely in acquaintance with a series of apparently unconnected facts, nor is it concerned only with methods of reasoning upon the actual facts of nature. Science is the system formed by building up these facts into one great structure, and though this structure is ever growing in extent and developing in detail, in such a manner that it is utterly impsssible for one mind to attempt to grasp the whole in all its marvellous intricacies, yet the intelligent student while devoting his energies to the study of some special part will ever remember that it is only a part of a great whole of which only a small portion is yet within the grasp of man, although even that small portion is far too vast to be mastered throughout by the individual mind, and he will endeavour to study that part which he has selected, not only in itself as if it constituted the whole of the building, but also in its relations to the other parts, upon the elaboration of which other minds are engaged. The science of pure or formal logic teaches us how to reason deductively, how to draw conclusions, but it does not concern itself with an inquiry into the data from which these conclusions are derived. When certain data are given pure logic simply teaches us to combine them in obedience to the laws of thought. Again, the science of pure mathematics starts with a small number of hypotheses of great simplicity, which until recently have been regarded as self-evident, existing in the mind as necessary truths independent of any actual or conceivable experience of the individual or his ancestors, or what Kant called synthetic *à priori* cognitions. Recently the attention of some of the foremost mathematicians of the age has been directed to the nature of these hypotheses, and they have been led to the conclusion that they are simply facts of experience. Lobachewsky, Riemann, Helmholtz, and others have shown that a perfectly consistent system of geometry may be built upon hypotheses differing from those assumed by Euclid, and if one of these other systems were to be really the one applicable to the space in

Digitized by Google

which we live, the fundamental hypotheses of geometry, such as "Two straight lines cannot enclose a space," would only appear to us to be universally true because of the smallness of the portion of space open to our observation, just as the surface of the ocean seems to be a level plain so long as we are restricted to a sufficiently small portion of it.

The processes of pure logic are applied to these fundamental assumptions, combining them together to give us fresh results, and as the number of results increases the operations for combining them become more and more complicated. The system of operations thus gradually built up constitutes the science of pure mathematics, which may be compared to an exquisite mill, and new mathematical discoveries, consisting of fresh combinations of operations to be performed upon the original data, may be considered as representing additions to and improvements in the mill work. The study of pure mathematics as usually taught simply instructs us in the manner of using this complicated machinery, while all questions as to how the data are obtained are generally considered to belong to the domain of the metaphysician rather than to that of the mathematician. The study of experimental science, of which we take physics as the type, opens up quite a new line. Here we are brought into contact with the actual facts of nature of infinite variety and diversity of aspect, and this it is, I repeat, which constitutes its great educational value, independently of the actual value of the knowledge obtained, great as that is. The student of physics is not asked to accept his facts upon the authority of his teacher or of a book. He is brought face to face with the experimental demonstrations, and compelled to accept them by the evidence of his senses. If the teacher does his work at all as it should be done the learner is taught to question every statement until Nature herself has satisfied him of its truth. He learns that the attitude of inquiry is the only one which will enable him to grasp those secrets which Nature retains so firmly until the patient inquirer forces her to yield them up. At first he will believe too readily, he will be too prone to draw general conclusions from particular instances without sufficient evidence; but, as he looks at the subject from different points of view, especially if under the guidance of a competent teacher, he will soon find that he has been too hasty, too ready to accept a conclusion without a thorough sifting of the evidence; in other words, too credulous. Through many failures he will gradually learn to regard the same thing from different points of view, and to carefully examine the evidence before receiving any statement or asserting the truth of any conclusion. Again he will find that the actual facts of nature are quite different from our experience of them. To take a familiar example, the physical phenomena producing in us the sensations of heat and light, which appear so different, really differ from each other no more than those which produce in us the sensations of musical notes of varying pitch; indeed, some of the vibrations are capable of affecting both sets of nerves, and so produce the sensations both of heat and light. The difference between the phenomena producing in our sensory organs the sensation of heat and the sensation of the colour red is of exactly the same kind as the difference between the phenomena producing the sensation of the colour red and the sensation of the colour blue. Again, the physical phenomenon is one which the mere sensations of heat and light would never have revealed to us, consisting as it does in the vibratory motion of a certain medium to which the name of luminiferous ether has been given. Whether this motion will produce the sensation of light or the sensation of heat depends simply upon the rapidity of the vibrations. We know that the slowest light-producing vibrations are those which give rise to the colour red, while the sensation of the colour violet is due to the most rapid of these vibrations. But, again, we find, not only that these vibrations produce two totally distinct kinds of sensation in us by affecting two distinct sets of nerves, according to the rapidity with which they follow one another, but we learn that some of these vibrations are able to affect both sets of nerves, and so produce in us the sensations both of light and heat. This gives us a striking illustration of that absence in nature of hard and fast lines of demarcation which becomes more and more impressed upon us as our study of physical phenomena grows more varied and extensive. Another question which will naturally present itself to us with regard to these vibrations is whether they have exactly the same effect upon the nerves of different persons; and if we pursue this inquiry we shall soon find that instead of uniformity there is infinite variety, as is forcibly exemplified in the case of what is known as colour blindness. This affords us an instance of another fact which it is important to bear in mind in the study of nature, viz., that a part of every observed phenomenon depends upon the observer, and we gradually learn by experience how far this factor is constant from one observer to another. We learn that for the different members of our own species this factor is fairly constant in its general character, but that in many instances there are variations in this general constancy as we pass from one individual to another, and therefore that the same fact may be differently recorded by two different individuals who are both perfectly truthful, simply because each of them could only report the result as it had affected his own sensory organs. Such lessons teach us to be diffident, doubting our own conclusions and those of others until the evidence for them has been thoroughly sifted and found to be satisfactory; they teach us to shun all dogmatism, and to refuse to accept any statement or conclusion until it has been fully tested.

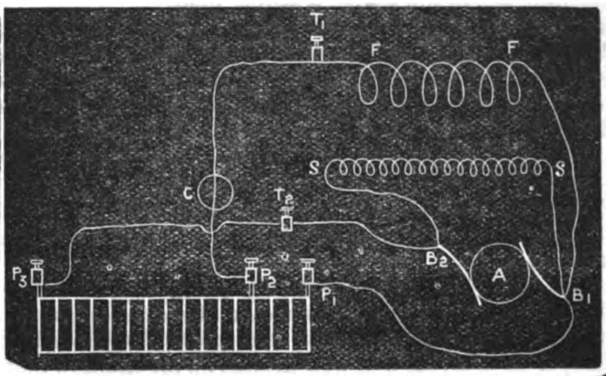
ON A NEW METHOD OF COUPLING DYNAMO AND ACCUMULATORS.

BY GISBERT KAPP.

It is a generally accepted belief that the only way to charge accumulators safely is by using a shunt-wound dynamo. If a series machine be employed, the danger of a reversal of current brought about through the speed of the engine decreasing, or the E.M.F. of the accumulators increasing, is so great that during the time of charging such a plant requires constant watching, or some special cut-out arrangement, which, upon the current weakening, breaks connection with the accumulators before reversal of polarity has actually taken place.

All this is, no doubt, true, if the series machine be connected to the accumulators in the usual manner—viz., the terminals of the one to the terminals of the other; but, by slightly altering this, the complication of a special cut-out arrangement and the danger of reversal of polarity can alike be avoided.

In the diagram (Fig. 1) A is the armature, B_1 and B_2 are



the brushes, F F the exciting coils of the field magnets, and T_1 and T_2 the terminals of the machine.

P_1, P_2, and P_3 are terminals of the accumulators, each terminal having a different potential; and the connections are made as follows:—

B_1 to P_1
T_1 to P_2
T_2 to P_3

Suppose B_1 to be the positive brush, then the potential in

Digitized by Google

P_1 is higher than that in P_2, and this again is higher than that in P_3.

$$P_1 > P_2 > P_3.$$

It will readily be seen that with this arrangement the potential in B_1 must always be greater than that in T_1, and therefore the exciting current must flow round the field magnets always in the right direction, no matter what goes on in the external circuit.

The difference of potential in P_1 and P_2 should bear a certain proportion to the resistance of exciting coils (R) and to the external current (C).

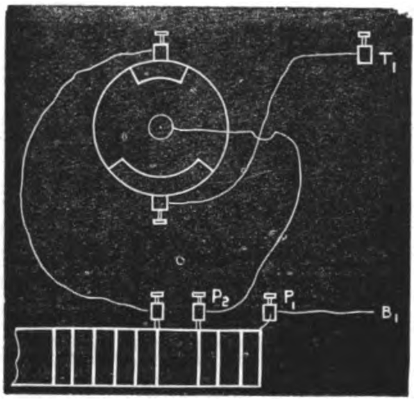
If $P_1 - P_2 = R\,C$, then the cells comprised between P_1 and P_2 will neither charge nor discharge, but as it were simply balance the E.M.F. necessary to drive the current round the field magnets.

If $P_1 - P_2 > R\,C$, the cells will partly discharge, and their discharging current will, jointly with the external current, excite the field magnets.

If $P_1 - P_2 < R\,C$, the cells will get charged; but, of course, at a slower rate than the rest of the battery.

It is best to make $P_1 - P_2$ as near as possible, though not quite equal, R C. For instance, say the machine is designed to give a current of 50 amperes — resistance of field magnets 0·1 ohm, then we would insert two cells between P_1 and P_2, making P_1 and $P_2 = 4·4$ volts, which will nearly balance the 5 volts necessary to drive the normal current round the field magnets.

In point C the special switch, shown in Fig. 2, should be inserted. The centre pin of this switch is connected to P_2, the wide lower contact piece to T_1, the narrow upper contact piece to the positive terminal of the cell standing next to P_2. The two contact pieces are made of different size, in order that the current round the field magnets should always begin to flow a moment before the main circuit is closed, so that the machine starts work with a strong field.



The arrangement above described will be found particularly handy in the case of small electric light installations in private houses, where a gas engine with dynamo and accumulators are employed. Of this I have recently had a striking example in the case of a small electric light installation of about 100 lights, put up in a private house in London by a well-known firm of electric light engineers, the name of which I will, however, not mention here, lest I should be accused of advertising my friends under the guise of a scientific article.

In this case a 3½ horse-power gas engine works a self-regulating machine (shunt coils shown at *s s* in the diagram), and this is coupled parallel with the accumulators and with the lamps. It is a *sine qua non* in such an installation that no skilled electrician should be required to work it, and in this case the duties of the attendant are extremely simple.

To start charging he has merely to turn on the gas to the engine, light the jet and switch on at C. The dynamo will then be driven as a motor by the current from the accumulators (which have sufficient charge left in them from the previous day), and thus cause the gas engine to start. After this the machinery may safely be left to take care of itself throughout the rest of the day, and in the evening, when the maximum of light is required, the dynamo and the accumulators are both feeding into the same lamp circuit.

CORRESPONDENCE.

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I must ask you to be good enough to allow me to offer some further remarks as to the experiments with a Schuckert machine, alluded to in my last letter, which were made to verify some very similar experiments described by Dr. Higgs in support of his contention that "the cutting of the lines of force may in practice be neglected," as a cause of E.M.F., and that "the inner wire is as efficacious as the outer wire." I prefer to quote Dr. Higgs's own words in order to put the matter clearly. He says:—"I dismounted a Schuckert machine, and causing the magnets to be set up on one side only of the ring, I revolved the ring at constant speed, and put current on to the magnets till there was no increase of E.M.F. I then caused the magnets on the other side to be set up and added; the increase of E.M.F. was about 2 to 3 per cent."

I think I may be excused for having understood this to mean that two poles on one side of the ring produced as great an effect as the usual four poles, minus 2 or 3 per cent.; the statement being put forward, as it was, in support of Dr. Higgs's views as to the efficiency of the Gramme form of machine, with its poles on one side only of the ring. My experiments showed, as I stated in my last letter, that with the magnets on both sides of a Schuckert ring the volt-amperes yielded by the armature were more than 100 per cent. greater than when two poles only were used, and that this proportion was maintained equally with weak and with saturated magnets.

In his letter of last week Dr. Higgs, referring to my remarks and experiments, says:—"When he added the two remaining magnets, he not only doubled his lines of magnetic force, but he also (according to his theory) doubled the wires cutting those lines. Of course, when he added his two remaining magnets, he should have *kept his total magnetism constant*. I am surprised he did not obtain a much greater increase than he reports." A criticism from such a point of view was unexpected. Had Dr. Higgs, in describing his experiments, said that he got about the same E.M.F. whether he used two strong poles on one side of the ring, or four weak ones placed in the usual positions—two on each side—I should have felt no surprise, as this result might have been expected.

But if I had kept the total magnetism constant, and found an equality of effects in the two cases similar to that obtained by Dr. Higgs, I fail to see how the experiments could have been taken to support the contention that the inner and outer wires are equally efficacious, and that "the cutting of the lines of force, considered as a cause of E.M.F., may in practice be neglected."

The experiment seems to show that under no circumstances can a ring armature like that of Gramme, with its poles on one side only, be as efficient as one having both sides exposed to direct inductive action. It points, I think, to conclusions directly opposed to those above alluded to.—Yours, &c.,

June 19, 1883. W. M. MORDEY.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am glad to see another letter on the above subject from one evidently well versed in electrical testing; and I am obliged to him for pointing out three sources of error in my communication to you of the 5th inst. Let me refer to these in their order.

1st. With regard to the resistance of the leading wires from conductor and main water earth to the resistance box—the "tare" let me call it. This was not allowed for in any of the tests I have recorded; for the reason that the wires were very short in the first one, making the resistance to be deducted insignificant. The tare was overlooked in the other two. The wires first used for testing No. 1 are fortunately still in the same position, so that I have been able to examine them. They measure together 33ft. 6in., are gutta percha

Digitized by Google

insulated, and have a resistance of ·103 ohm. In testing Nos. 2 and 3 conductors the wires were much longer, but as I cannot now ascertain the length or recover the wires I cannot measure the resistance.

2nd. "A. J." objects to the battery I used. I am sorry I have not a Daniell beside me, and cannot, therefore, make the experiments he proposes; but I do not think the current is flowing long enough at one time to make much difference, especially when we consider,

3rd. That with the galvanometer which I employed (a Silvertown Post Office upright pattern) I was unable to detect any current when the *leaden* and *cast-iron* earths of No. 1 were in circuit with it alone. Neither did it indicate any difference between + and – currents sent through the bridge.

I have examined the copper band round the cast iron-pipes for Nos. 1 and 2 conductors, and find nothing wrong with either of the pipes. No. 1 is in a dry situation, No. 2 is in a well, though not covered with water, both can be easily seen. No. 3 is buried about 20ft. below the surface, and cannot be got at without considerable excavation. When it has done duty for a couple of years I will have it examined.

I am engaged repeating my tests, but have not had time to complete them; when finished I will communicate with you. Meantime, I would like your correspondent "A. J." to give the results of his lightning conductor tests, with the different earths be used; and to explain also for the benefit of your readers what he means by the "*Absolute* resistance in ohms to earth of the lightning conductor."—Yours, &c.,

Greenock, 19th June, 1883. T. L. P.

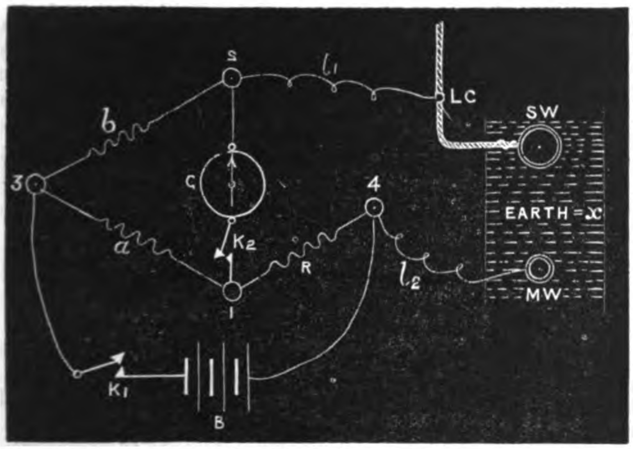
TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

[The following correction arrived too late for insertion in our issue of last week.—Ed. *E.*].

Sir: Please cancel in my letter part *under heading marked* 1, and substitute the following:—

1. Before soldering on his two No. 16 B.W.G. leading wires to his lightning conductor (L.C.) and main water earth (M.W.), he should have joined them together and found their total resistance by the Wheatstone bridge method, and subtracted this amount from the result obtained when testing for the resistance to earth of his lighting conductor in order to find the true resistance between his lightning conductor, earth (S.W.), and the battery earth (M.W.), as seen by the following diagram:—



Where L C represents the lightning conductor attached to
S W „ the cast-iron water pipe,
a and b „ the arms of the Wheatstone bridge,
R „ the resistance required to balance,
l_1 and l_2 „ the leading wires plus the resistance between
M W „ the main water pipe or earth for
B „ the battery, and S W the earth for lightning conductor,
K_1 and K_2 are the keys for manipulating the current, and
G represents the galvanometer.

Now let X equal the resistance between the points 2 and 4 in the above diagram, that is the resistance of leading wire l_1, plus lightning conductor from attachment at (L C) to (S W), plus ground or earth resistance between the pipes (S W) and (M W), plus lead l_2, then when balance obtained

$$a : b :: R : X$$
$$X = \frac{bR}{a}.$$

From X we must subtract the resistance of the leading wires, that is $l_1 + l_2$, in order to get the true resistance from point of attachment at (L C) to the leaden water pipe (M W), *i.e.*,

$$X - (l_1 + l_2).$$

—Yours, &c., A. J.

HISTORY OF TELEGRAPHS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In a note in your last week's issue relating to discoveries made by the late Abbé Laborde, reference is made to the "mysterious passage" in the Book of Psalms, "*Fecit fulgura in aquas*," of which the writer gives a lengthy rendering. We are to gather from the interpretation that the author of the Psalms had a scientific knowledge of the subject which has remained hidden from his time to that of the Abbé. I fully believe there are many passages in the Scriptures which will prove that the writers, by inspiration or otherwise, were better acquainted with various branches of science than is generally supposed. Be this as it may, the only passage—at least in the Protestant version of the Psalms—that corresponds with the Latin quotation abovementioned is in the 7th verse of the 135th Psalm, "He maketh lightnings for the rain." Is this the passage referred to by M. l'Abbi Moigno?—Yours, &c., F. S. B.

Charlton, June 18, 1883.

LITERATURE.

Formulaire Pratique de L'Electricien. Par E. Hospitalier, Professeur à L'Ecole de Physique et de Chimie Industrielles de la Ville de Paris. G. Masson, Paris.

Elektrisches Formelbuch. Mit einen Autrauge suthaltena die Elektrische Terminologie in Deutscher, frauzösischer und Englischer Sprache. Von Professor Dr. P. Zech. A. Hartleben. Wien. Pest. Leipzig.

Quite a crop of books containing electrical formulæ are now appearing, but we do not think that the first editions are very promising. We hold that in two necessary features the works before us will fail to satisfy the practical man. Books of this kind should be handy in form, and have a thoroughly good index. Molesworth is far superior in both respects. The work of M. Hospitalier is more comprehensive than that of Professor Zech, including, as it does, formulæ relating to algebra, trigonometry, and other branches of physics, besides electricity. Both compilers seem to have consulted the best text books and publications upon the subject. We should say that both works contain too much letterpress, and that such paragraphs as those on "Procédés d'Aimutation," in M. Hospitalier's work, might well give place to other matter. So far as we have examined these works they contain much that is useful and valuable, and the few words we have said are intended more to suggest improvements in the next edition than to criticise adversely. Let the authors assume that the electrical engineer has some knowledge of electricity, and restrict themselves to the giving of figures and formulæ generally used and not easily remembered. We should have said that a good feature in Dr. Zech's work is the giving in an appendix the nomenclature in German French, and English.

Digitized by Google

ON THE DEVIATION OF THE STANDARD COMPASS IN H.M. SHIPS OF WAR.

"The magnetic character of the armour-plated ships of the Royal Navy," was the subject of a paper by F. J. Evans, Staff Commander, R.N., F.R.S., and Archibald Smith, F.R.S., read before the Royal Society in March, 1865.

This paper gave the first published results of the system of observation and analysis of the deviations of the compass then recently introduced. These results showed the magnetic character of a large number of armour-plated ships from the date of launching until they were complete and had been at sea in English waters for some time.

As their longest voyages were to Lisbon and Teneriffe, and the alternative (to a large change of magnetic latitude) of keeling the ship could not conveniently be carried out, the relative proportion of hard and soft iron producing the deviation in their standard compasses could not be ascertained.

It may also be here remarked that none of the compasses referred to in the paper of 1865 had either magnets or other mechanical correctors applied to them.

During the present session of the Royal Society a paper* has been read treating of the relative proportions of hard and soft iron affecting the standard compasses of six classes of Her Majesty's ships, and the changes which take place in their deviations on change of magnetic latitude.

Of the twenty-five vessels the observed deviations of which have been discussed in this paper, six were iron armour-plated, four iron cased with wood, three iron troop-ships, three steel and iron cased with wood, seven composite built, and two wooden vessels with iron beams and vertical bulkheads.

The deviations discussed were observed after the vessels were fully equipped and ready for sea, after long, full-power trials with powerful engines, and consequently to be considered in a state of magnetic stability. Each vessel had also made voyages to places involving considerable change of magnetic latitude from that of England.

Also the semicircular deviation of all these vessels was corrected in England by a bar magnet or magnets fixed in the compass pillar.

From the constancy of the magnetic moment of these correcting bar magnets, they may be considered as the introduction of a permanent and independent magnetic force acting in opposition to the forces produced by the permanent and sub-permanent magnetic forces of the hard iron in the ships.

One of the important results of a knowledge of the constants for soft iron is the power which it gives of predicting for certain vessels examined, and others of the same class, the probable changes which will take place on change of magnetic latitude. Further than this, should it be decided to use a Flinder bar to correct the constant proceeding from induction in vertical soft iron, such a bar could be placed in any of the vessels examined—or those of similar construction—before leaving England, with the reasonable prospect, for example, of the correction being found nearly as complete at the Cape of Good Hope.

Semicircular Deviation.

Semicircular deviation from fore and aft forces is due to three causes:—

(1) A large proportion proceeds from permanent magnetism in hard iron, and may therefore be reduced to zero for all latitudes by a permanent magnet.

(2) A small proportion is caused by sub-permanent magnetism in hard iron. Sub-permanent magnetism diminishes slowly by time, but it is also subject to change from the following causes:—

(*a*) From the ship remaining in a constant position with regard to the magnetic meridian for several days.

(*b*) From concussion.

(*c*) A greater change is experienced from a combination of these causes.

On the removal of these sources of disturbance (*a*) (*b*) (*c*) the deviation gradually returns to its original value.

(3) The principal cause of change of deviation on change of magnetic latitude arises from vertical induction in soft iron, which varies directly as the tangent of the dip. When the compass is properly placed with respect to surrounding vertical iron the deviation from this source is of small value.

Semicircular deviation from tranverse forces is subject to the same laws as that from fore and aft forces, but as the iron is generally symmetrically placed on each side of the standard compass position it is exceptional to find any part of it arising from vertical induction. This part of the deviation, therefore, is chiefly due to permanent magnetism in hard iron, with a small part due to sub-permanent magnetism. It has generally been found that the changes of deviation from sub-permanent magnetism acting in the transverse direction are greater than those in the fore and aft direction.

To ascertain the full value of changes in the sub-permanent magnetism, observations should be immediately taken on the removal of the inducing cause.

Quadrantal Deviation.

Quadrantal deviation, which proceeds from horizontal induction in horizontal soft iron, does not change with a change of magnetic latitude. It decreases, however, during the first year or two after a ship's completion, when it becomes nearly permanent.

It has been found in all modern vessels of war, that the mean directive force of the compass needle is less than on land, generally by about a tenth to the twentieth part, but sometimes attaining a value of three tenths in diminution at the time of launching. It improves slowly by lapse of time, and finally assumes a permanent value.

Relative Proportions of Hard and Soft Iron.

It has been found that the relative proportions of the hard and soft iron affecting the standard compasses of the twenty-five vessels examined differ considerably, even in ships of similar construction.

This difference may be accounted for by the compasses not being placed in the same relative position in the ships considered as magnets of various forms, and containing numerous iron bodies introduced during equipment.

It might have been expected that in those ships in which steel enters largely into their construction, that the deviations would have been less liable to change than in the ordinary iron ship. Such, however, has not been found the case, as the steel used—known generally as mild steel—has only ·2 per cent. of carbon. The conclusions which have been arrived at in this paper point to the conditions which should govern the selection of a suitable position for the standard compass with regard to surrounding iron in the ship.

* "On the Changes which take place in the Deviations of the Standard Compass in the iron armour-plated, iron, and composite built ships of the Royal Navy on a considerable change of Magnetic Latitude, &c." By Staff Commander, E. W. Creak, R.N., of the Admiralty Compass Department. March, 1883.

THE ELWELL-PARKER ACCUMULATOR.

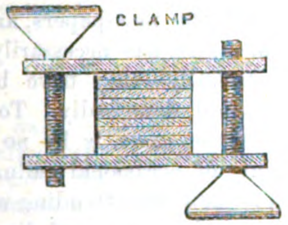
The Wolverhampton Electric Light, Storage, and Engineering Company is now manufacturing and selling a new storage battery, of which very little has yet been heard, but which appears to be one of considerable promise.

About the same time that M. Planté made his remarkable discovery, Mr. Bedford Elwell and Mr. Parker, of Wolverhampton, hit on nearly the same thing. They found that by immersing lead plates in a dilute mixture of nitric and sulphuric acid very important advantages were secured. M. Planté and Messrs. Elwell and Parker patented their inventions about the same time, and now work together.

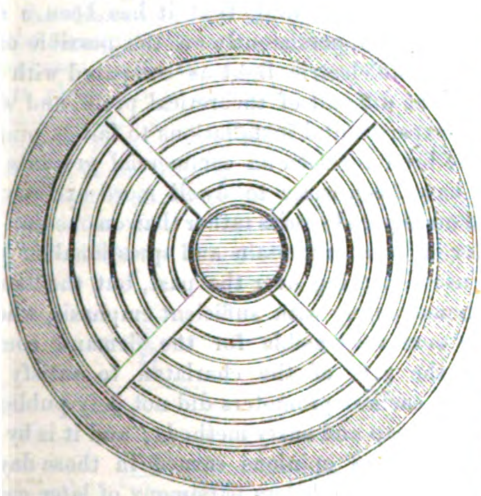
The method of making the Elwell-Parker secondary battery may be thus described:—Strips of sheet lead 9in. wide and any convenient length, weighing 2lb. to the square foot, are passed through a machine which first punches holes entirely through them and then impresses

Digitized by Google

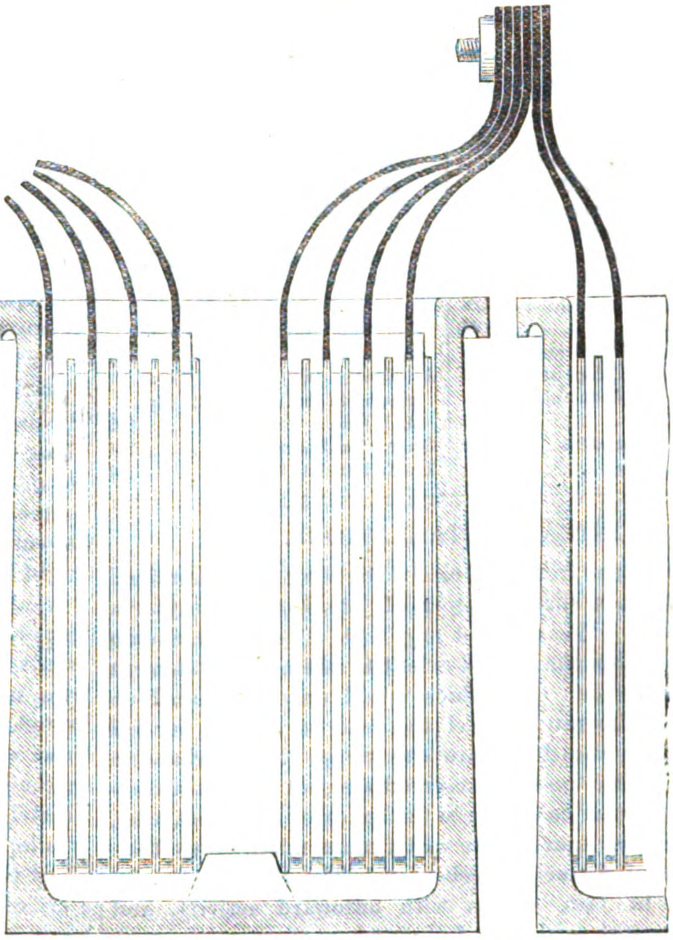
them with indentations, which act as distance pieces to keep the layers of each plate apart. The holes secure a free circulation to the electrolyte. These strips are then rolled spirally into cylinders containing, in the small cells, three thicknesses of plate each, the joints being made secure by fusing with a soldering iron, and an anode of much thicker lead being fused on at the same time. Each cell contains eight of these cylinders $\frac{1}{4}$in. apart. The lead cylinders are first placed in a bath containing a dilute solution of nitric and sulphuric acid, and left there for twenty-four hours. The effect of this bath is to minutely honeycomb the lead plates, putting them into the most favourable condition for "formation" by the electric current. There is also formed upon the surface of the plates a deposit of sulphate of lead, the greater part of which is subsequently reduced to peroxide, part of it being first washed off. The plates on being taken from the bath are washed, and then generally used, but the company manufacturing under the patent also uses wood cells, coated inside with a composition of gutta percha, which are preferable where strength and lightness are required. The quantity these cells will give out at an electromotive force of two volts or rather more—same as the original Planté cell—is about 40 ampere hours when sent from the works, that is, supposing an accummulator is required to give a current at an electromotive force of 45 volts, twenty-two of these cells will give a current of 10 amperes for four hours before any of the cells "give out." But the capacity of the cell may be greatly increased by occasionally reversing the charging current, as in the original Planté cell. The arrangement of the battery is very workman-like and convenient. A cell can be taken to pieces and put together again in about two minutes, and the way in which the cylinders are put together gives great stiffness and prevents deflection or bending, while the plates being free to expand



CLAMP



PLAN



SECTION

placed in the ordinary dilute sulphuric acid solution in the cell. They are then charged in one direction for six hours with a current of 12 amperes, discharged in about three hours through ten Swan 45 volt 20-candle lamps—twenty-two cells give 45 volts—and charged again in the reverse direction. They are then ready for use. There is then no sulphate visible, the peroxide plate being a rich, dark brown colour, of smooth, hard, crystalline appearance, and the negative plate presenting a clean surface of ordinary lead colour.

The accompanying engraving shows one cell and a portion of another, coupled by clamping the electrodes together. The plates or cylinders are retained in position by notched vulcanite frames underneath, and notched distance pieces of the same material on the top, thus leaving the entire space between the plates and a space underneath them open for the free circulation of the electrolyte. Earthenware cells are or contract can do so without losing their shape, which is much more than can be said of most batteries of this class.

The proprietors inform us that last week they took a cell to pieces, one that had been at rest for two months after working regularly for some months previously. They found the plates all clean and smooth, and without a trace of sulphate. The resistance of these cells is extremely small, and no fall is noticeable in the E.M.F. from the first instant of closing the circuit to the time when the first cell "gives out," unless too many lamps have been put in circuit at once. The proprietors state that they have taken out 12 amperes for $2\frac{1}{2}$ hours from a 24 cell battery of this construction without any perceptible fall; and that after a rest of 24 hours they obtained the full E.M.F. again. These cells are now being practically tried with apparently very good results on the Bush Hill Park Estate, near Enfield.

CHEAP INSTALLATIONS.

The most ardent friends of electric lighting are constrained to admit just now that its career, of late, has been rather a checkered one. We will not say that it is fallen among thieves, for within the limited extent to which that statement might be true our sympathies would only be wasted on people who deliberately travel the road to Jericho in bad company. But the dupes are one thing, the merchandise is another. What we do unreservedly regret is that latterly the new illuminant has got into the hands of hucksters, who, if a degree less knavish, are vastly more mischievous than any number of financial freebooters. The cheap and nasty phase has, in fact, set in with untoward activity, and threatens us with mishap or failure where success might be confidently assured. Cheap machines, cheap appliances, and cheap workmanship are being manufactured or imported in alarming quantities; and nasty exhibitions, futile experiments, and bogus installations are the results. It is not to be wondered at, therefore, that in certain quarters the cry is heard already that the electric light is not only expensive, but inefficient, inadequate, or untrustworthy.

Several causes have been at work to bring about this state of things. First, there is the unwholesome but prevailing tendency to undersell whatever is on the market, and underselling in the case we are considering means, almost of necessity, inferior qualities of one kind or other. Next, there is the undeniable fact that great and perhaps inordinate expectations had been roused in respect to the comparative cost of electric lighting—expectations which, being so extravagant, were doomed to disappointment. Then, again, one after another, fresh systems and appliances have been put forward with inconsiderate haste, whose promises have speedily failed of fulfilment in private, and afterwards more disastrously in public—failed, we mean, in the matter of cheapness, for as regards their performance the public were more than satisfied, they were enthusiastic. Lastly, there was the share market to satisfy or appease. It had opened with the customary programme, and with more than its customary recklessness or ignorance. The result followed that, with a capital commodity for sale, vendors could not find customers except by charging more than their published prices or selling for less than cost.

Then comes the inevitable huckster who undertakes to set matters right by offering a very cheap article. Invention can practise its ingenuity in this direction, of course, as well as in any other, and we are far from saying that the direction of cheapness is one not to be taken when the path leads to efficiency as well. But when cheapness alone is the thing aimed at, as has obviously been the case of late, efficiency will be in inverse proportion to price. Some machines that have recently come under our notice, and have made a great stir in the newspapers, are certainly in this category. The same spirit has necessarily extended itself to the installations generally—they have been done cheaply, and, it is needless to add, done badly. To say nothing of the danger, which in certain cases is by no means imaginary, there is the certainty of occasional failure, and the risk of utter collapse at any moment, attending work carried out in this spirit, and the equal certainty of discrediting the whole business. But the promoters have secured their ends for the time, they have created a cheap commodity, and have found a market for it.

Now, we venture to think that it has been a mistake all along to dwell so persistently on the possible or probable cheapness of the electric light as compared with gas. The contention was difficult of theoretical proof, and was sure in the earlier experimental installations to fail in practice. This might have been foreseen on commercial grounds alone, and it would have been wiser to dwell more exclusively on its many and undisputed merits rather than on one that was, at all events for a time, uncertain and questionable. It is, perhaps, no use lamenting over the past, but the lesson is now brought home, surely with sufficient emphasis, when we see those who were responsible for the demand compelled to descend to the arts of the charlatan to satisfy it. Fortunately, the earliest promoters did not defy public disfavour by adopting cheap and nasty methods; and it is by no means likely that the good opinions earned in those days will be sacrificed by the thoughtless parsimony of later competitors. Their well-deserved failure is certain; the best friends of electric lighting may fervently hope it will be speedy.

One main cause of the vicissitudes experienced by the new illuminant has been due to the public trusting the commercial rather than the scientific adviser. The scientific world is not responsible for the extravagant expectations above commented on, nor for the questionable means adopted to secure the temporary patronage of the public. If promoters and shareholders alike would once for all recognise the fact that this is a scientific subject, and that nobody but men of knowledge and experience are fit to be trusted with the business of electric lighting, there would be an end to accidents, failures, and disappointments. We are sure that no competent scientific adviser would give his countenance to bad machines or scamped workmanship; and the investing public, when invited to embark capital in a cheap concern, would do well to assume beforehand that it will be conducted unscientifically, and is therefore bound to fail.

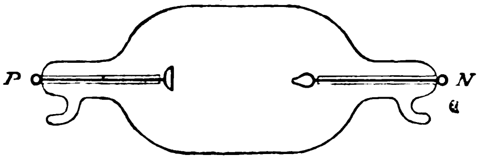
EXPERIMENTAL RESEARCHES ON THE ELECTRIC DISCHARGE WITH THE CHLORIDE OF SILVER BATTERY.*

BY WARREN DE LA RUE, M.A., D.C.L., F.R.S., AND HUGO W. MÜLLER, PH.D., F.R.S.

The authors recall that at the conclusion of the third part of their researches,† they stated that they intended to make an investigation on the dark discharge, and the special conditions of the negative discharge. This paper contains a number of experiments, more especially on the latter subject, and also others intended to throw light on the general nature of the electric discharge through gases.

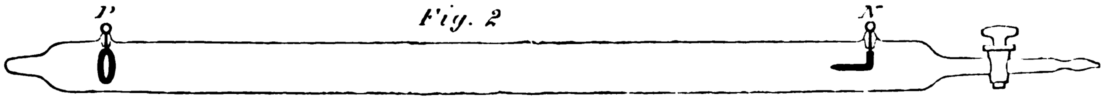
The first part of the paper describes some experiments made with vessels of different forms in order to ascertain whether the dimensions and shape of the vessel have any effect on the pressure of minimum resistance to the electric

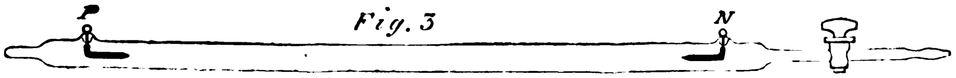
Fig. 1



discharge. This was found to be the case, for example, with a residual air charge in a spheroidal vessel 7in. (17·8 centims.) long, and 5in. (12·7 centims.) diameter (Fig. 1). The pressure of minimum resistance was as high as 3 millims., 3,947 M; while in a tube 22·5 inches (57 centims.) long, and 1·625 inch (4·1 centims.) diameter (Fig. 2) it was only 0·69 millim., 908 M. Again, in a smaller tube 23 inches (58·4 centims.) long, and 0·75 inch (1·9 centim.) diameter (Fig. 3), it was 1 millim., 1,316 M. It is evident, therefore, that not only the dimensions of the tube, but possibly also the shape of the terminals, have an influence on the pressure of least resistance, and it is very probable that in the atmosphere where lateral expansion is practically unlimited, the conditions of minimum resistance are different from those which exist even in very large tubes, and that this may influence the height of the aurora.

The paper next deals with the discharge in miniature tubes $\frac{7}{8}$ inch (2·2 centims.) long, and $\frac{1}{4}$ inch (0·63 centim.) diameter, with terminals nearly touching (Fig. 4). At first it



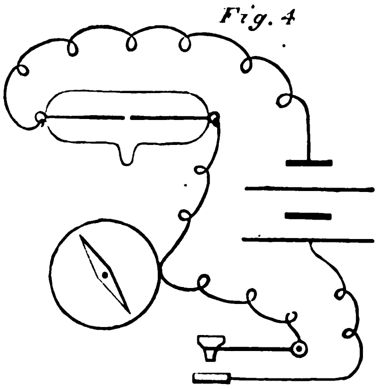


required 2,400 cells to pass, then a single cell would do so, but after standing a short time it required 4,800 cells to reproduce a discharge. In another tube 1$\frac{3}{4}$in. (4·4 centims.) long, and $\frac{3}{8}$in. (0·95centim.) diameter, with the terminals distant 0·00104in. (0·0264millim.), it required 2,240 cells to produce a discharge. Then the potential had to be increased to 11,240 cells to do so. Ultimately even this number failed, but after the tube had lain by for some days, 600 cells could pass. It is very possible that the strong discharge in the first instance volatilised a portion of the terminals which were of platinum, and that this volatilised metal condensed afterwards, or else that the terminals absorbed the gas so completely as to produce a vacuum too perfect to admit of a discharge taking place; and that, ultimately, sufficient of the occluded gas was again given off to render it again possible.

In connection with the occlusion of gas by terminals, a case is described in which the terminals are of palladium, and the charge hydrogen (Fig. 5). After a few discharges the terminals occluded some of the gas, and when a fresh one was produced, a volatile compound of hydrogen and palladium was given off, especially from the negative, and produced a dense mirror-like coating on the inside of the tube (Fig. 6); this was re-occluded by standing for a couple of days, leaving the tube free, and again given off to form a new mirror-like coating with a fresh discharge; this property has continued since March, 1875.

The paper next describes experiments to ascertain the length of the spark in dry air and in air saturated with moisture. It was found to be practically the same in both cases. With 10,860 cells the mean length of the spark between two paraboloidal points was found to be in dry air 0·45in. (1·1centim.), in moist air 0·447in. (1·1centim.).

Fig. 4



The next subject taken up is the discharge in a tube from two batteries, first in the same, and then in contrary directions. In the tube are two terminals at each end, one pair at opposite ends being enclosed in two short pieces of tube, 9in. (22·8 centims.) long, and $\frac{1}{2}$in. (1·27 centim.) diameter; the main tube being 31in. (95·2 centims) long and 1$\frac{3}{4}$in. (4·4 centims.) diameter (Fig. 7). The various phases of the stratified discharge are represented in an engraved mezzotint steel plate copied from photographs, and show the effect of the one stratified discharge on another stratified discharge produced by a second battery. It is seen that two discharges in contrary directions may take place in the same tube, and that the one modifies the aspect of the other.

Experiments are also described in a tube in the form of a cross with four arms at right angles (Fig. 8), with two separate batteries connected in various ways with the different members. The experiments were made both in air and in hydrogen. By the introduction of external resistance in one of the batteries, the discharge could be readily identified as belonging to that battery by the effect of the resistance on

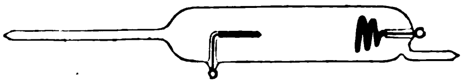


Fig 5.

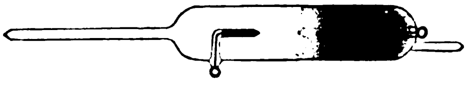

Fig. 6.

the character of the stratification. In one of the mezzotint plates are several figures copied from photographs which show clearly the phenomena produced. Calling the poles P and N of one battery, A, and P′ and N′ of the other, B, it is shown

* Abstract of a Paper to the Royal Society.

† *Phil. Trans.*, Part I., Vol. 171.

Digitized by Google

in one case when two currents were equal, 0·0083 ampere, that a discharge from A battery goes from P in the direction of N only so far as the junction at the cross and then turns off to N′, the negative of the other battery B; while, on the other hand, the discharge of the B battery goes from P′ to N of the A battery. The case is different if an external resistance is introduced in one of the discharges, reducing it to 0·00087 ampere, then the discharge of the A battery goes from P to N, and that of the B battery from P′ to N′. There is a bending down, however, of the strata of the weaker discharge at the cross junction, in consequence of the action of the stronger one.

The authors remark that one cannot but be impressed, from the experiments described in the paper, and others in their former papers, by the apparent plasticity of the aggregate assemblage of molecules constituting a stratum which yields to external influences that modify its form.

The authors describe and figure a case of complex strata in the form of an outer bracket convex towards the negative, and close to it an inner chord; also discharges in various gases in tubes of large dimensions, 37in. (94 centims.) long and $5\frac{13}{16}$in. (14·8 centims.) diameter. In these the stratification, which is comparatively narrow at the terminals, extends in a conical form from the terminals to the full diameter of the tube.

They have found that the dark space in the discharge in vacuum tubes is only relatively actinically dark in comparison with a stratum, and they succeeded in obtaining a photograph of the dark space in thirty-five minutes as strong as that from a stratum in two and a half seconds; consequently, they conclude that the dark space is 840 times less actinically bright than a stratum.

The authors next describe a number of experiments, by means of a Thomson-Becker electrometer, used on a method, to avoid leakage, proposed to them by Professor Stokes, to ascertain the difference of potential in different parts of a vacuum tube having a number of rings sealed within it, also in other tubes of special construction. These bring out instructive information, not only in reference to the relative resistances of different lengths of a column of gas at various pressures, but also bring out forcibly the impediment presented by the terminals themselves to the passage of a discharge from gas to terminal and terminal to gas.

It is shown that, at moderate exhausts, the resistance to the passage of the discharge is uniform along the length of the column of gas, and that at high exhausts it is not so, and that the total resistance increases but slightly with an additional length of the column; moreover, that at these low pressures the main impediment is in the passage of electricity between gas and terminal or terminal and gas. This is much greater at the negative than at the positive terminal.

The authors have next studied the electrical condition of a gas in the immediate vicinity of the negative terminal. In order to do this they constructed a tube 4½ inches (11·4 centims.) long, and 1⅞ inches (4·8 centims.) diameter. One terminal is in the form of a point, the other in the form of a ring. The positive pole of the battery was connected with the point and the negative either to the ring or to earth. The ring terminal of the tube was, when the battery was insulated, connected with earth either by means of a stout wire or three feet (91·4 centims.) of fine platinum wire 0·002in. (0·005 centim.) diameter, and offering a resistance of 81 ohms, or a moistened cork offering a resistance of 4,300,000 ohms. In the tube were sealed three idle wires, 1, 2, 3, covered, with the exception of their extremities, with fine glass tubing (Fig. 10). No. 1 idle wire is 0·02in. (0·005 centim.); No. 2 0·2in. (0·5 centim.); and No. 3 0·6in. (1·5 centim.) from the ring. The ring terminal, when connected to earth, was found to be always at zero potential. Notwithstanding this there was frequently observed, more especially as the exhaust was increased, a negative potential when the idle wires were connected successively with the electrometer, amounting in one case with an air charge, pressure 0·01 millim., at wire No. 2, to 1,068 cells, at wires 1 and 3 to 912 cells. At other times a plus potential was observed. Many experiments were made to determine the precise conditions which developed a negative potential or a positive potential, but unsuccessfully, and it was inferred that this depended on the condition of the discharge itself within the tube. It is certainly very remarkable that while the potential of the negative ring was absolutely zero, that a high negative potential should be developed in its near vicinity.

The authors remark that every one familiar with the appearance of a stratified discharge will have noticed, when the negative terminal is a ring, that as the exhaust proceeds a spindle of light approaches, and at last protrudes through

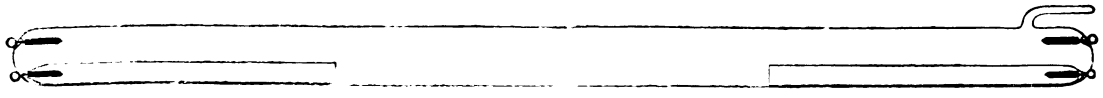

FIG. 7.

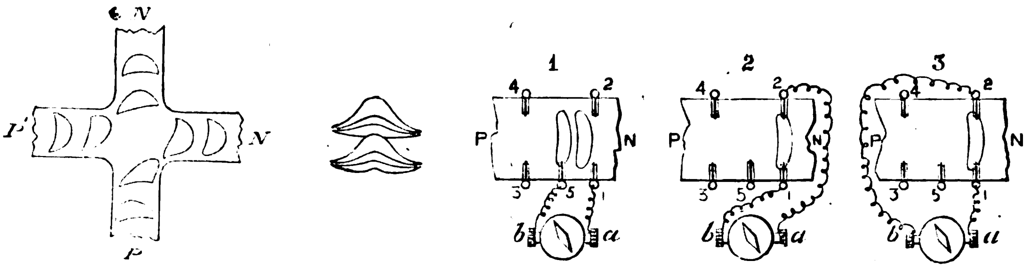

FIG. 8.

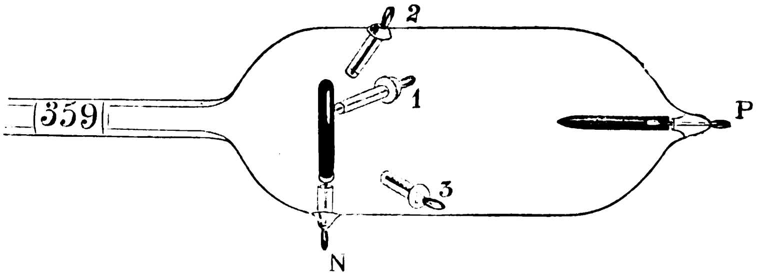

FIG. 10.

Digitized by Google

the interior of it (Figs. 11, 1, 2, 3, 4, 5). This spindle they regard as a visible exponent of strong action among the molecules of gas composing it. In order to probe its electrical condition, they prepared a tube with a central idle wire, surrounded by a minute glass tube, except its extremity, and projecting to a distance of $\frac{3}{8}$in. (0·95 centim.) from the plane of the ring, which was made negative. Another idle wire was sealed in the tube 0·15in. (0·38 centim.), from the periphery of the ring. As the exhaust proceeded with a charge of carbonic anhydride, the spindle approached the ring, and ultimately protruded through it. It was found that the potential of the central idle wire increased with the exhaust, until it nearly or quite equalled that of the whole tube; while that of the external idle wire was only 0·054 that of the tube.

A great number of experiments were made to test the potential across a stratum *a*, *b*, and across a dark space *c*, *d*, respectively, by two idle wires sealed in suitable positions in a tube, one of which was connected with earth, the other with the electrometer (Fig. 11, 6). The gases used were carbonic anhydride and hydrogen respectively. As a mean of a great number of experiments it was found that when a dark space was straddled, the potential being reckoned 1, then when a stratum was straddled, the potential was 1·243, 1·229.

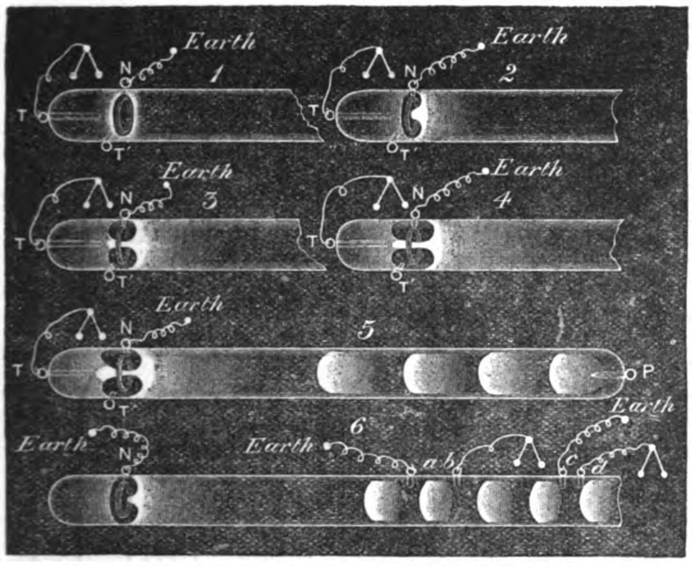

FIG. 11.

On testing two idle wires distant $\frac{5}{8}$ inch (1·6 centim.) apart with a Thomson galvanometer, the current in this fractional part of a tube was found to go frequently in the reverse direction to that of the main current, and when the galvanometer was connected to two idle wires diametrically opposite, currents were indicated sometimes in one direction, sometimes in another, across the tube. These experiments seem to indicate that there are eddies in the gas during a discharge, as if the motion of the molecules conveying an electric discharge was of an epicycloidal character. The authors conclude by saying that it is possible that the eddies may be connected with the production of strata.

PRACTICAL TELEPHONY.

(CONTINUED FROM PAGE 114.)

THE TRANSMITTER.—The instrument principally used in this country is known as the Blake transmitter, which acts by varying the resistance of the local or battery circuit by means of a platinum point pressing against a hard carbon button. The sound waves strike the diaphragm and cause the platinum point to vary its pressure against the carbon button, thus producing undulations in the current strength similar to that described when speaking of the telephone. As the current flowing in the local or primary circuit is much greater than that generated by a telephone, the volume of sound in the receiving telephone is sufficient for all practical purposes; the current of the battery circuit is not, however, allowed to go to line, for reasons to be hereafter explained.

Figs. 22 and 23 show the interior construction of a Blake transmitter. Similar figures or letters show similar parts. A is the mouthpiece forming part of the case, B a cast-iron frame, C an iron lever carried by the spring L and adjustable by screw *d*. This lever carries the spring and brass carbon holder F and carbon button G. It also has attached to it the insulating block H, through which passes the spring carrying the platinum point *e*. This point should follow the carbon button about half an inch if the carbon is pulled back. D shows the diaphragm of thin sheet iron, having on it an insulating rubber ring E. K is a steel spring or damper pressing on the diaphragm D, but prevented from making electrical contact by means of a small rubber glove placed in its extremity. The induction coil is shown at M. The case is hinged at I J. The local circuit through the transmitter is as follows:—The current from local cell enters at terminal 2, passing through primary of coil, the hinge J, wire *b*, frame B, spring L, lever C, spring and carbon block F G, platinum point C, wire *a*, and hinge I, to terminal 1. The telephone circuit enters at terminal 3, passes through the fine secondary wire of coil to terminal 4. The primary wire should have a resistance of about half an ohm, and the secondary about 250 ohms. According to theory the resistance of the secondary should equal that of the line, but in practice it is not always so, for on a line of nearly 1,800 ohms resistance the best effects were produced with a secondary wire of only 30 ohms resistance. The induction coil M, shown in section, Fig. 24, is used because the range of variation of resistance between the carbon button and platinum point would be small compared with the total line resistance, and therefore would give rise to very small undulations in the current, but the same variation produces very great changes in the low resistance primary circuit, and therefore great variations in the current. The secondary current has also the power to overcome a very high line resistance.

TO ADJUST A TRANSMITTER.—In the first place, if it is a new instrument just set up, see that the paper padding is removed from between the carbon block and the frame. Place the telephone to your ear, and tap the diaphragm. A sound should then be heard in the telephone, if connected up rightly. If the sound is dull and short, slacken back the screw *d*. When rightly adjusted a clear, musical sound should be heard, but leaving off sharp. If it seems inclined to be prolonged, or makes a humming noise, the screw must be tightened up a little. Do not at any time move the screw more than a quarter of a turn at a time, or the best position may be passed. If you have an operator at the other end of the line call up and speak. In a well-adjusted transmitter breathing against the diaphragm should be heard, and in a quiet place, speaking in a whisper, should be heard at the other end.

Some allowance should be made for the voice of the person who will usually use the instrument; but, in any case, do not leave the adjustment too loose, or it will jar, and probably commence humming in a few hours, as a newly set-up battery becomes more active as the solution becomes saturated.

THE SWITCH BELL.—It is needless here to go into detail of the various forms of switch bells that have been used from time to time. Those first used consisted of a bell and a switch, which was moved from *ringing* to *speaking* side by hand. This was improved upon by causing the weight of the telephone, when placed on the hook, to hold the switch connected with it in contact with the bell circuit. When the telephone was removed, the hook was drawn by a spring into contact with the telephone circuit, the switch hook itself being in permanent connection with the line.

This form answered all that was required during the time that telephones were used both as transmitters and receivers. The advent of the battery transmitter, however, necessitated an additional arrangement that would automatically open and close the local circuit of the transmitter. After many modifications it assumed the form shown in Fig 25. A B shows the case, C the bell, D the hammer, E E' the magnet coils, F F the iron bell frame, I J K hinges and contact springs (the latter to ensure good connections), L ringing spring, M contact bracket, N battery contact post, O ivory ringing button, P bell contact post, Q switch hook disc, R switch hook, S local circuit contact spring, T' local circuit contact stud, T Z terminal to be connected to zinc of local cell, C terminal for carbon of battery, L do. for line, E do. for earth connection; 1, 2, 3, 4 terminals to be connected to the corresponding numbers in transmitter, 5, 6 terminals for telephone cord; *a* armature to contact spring of bell, *b* adjusting screw for bell, *c* armature, *d' d'* poles of magnet, *e* screw for attaching end of coils to iron frame, *f* contact between M and L (*normal position closed*), *g* contact between L and N (*normal position open*), *h* ivory pin for lifting spring S from contact T when telephone is hung up, *i* bell switch contact spring and post,

Digitized by Google

k k′ platinum contact points for *i* and *j*, *m* spring for raising switch hook, *o* screw of switch disc. The passage of the current when receiving a call signal is as follows: (see also small diagrams in Fig. 25) Entering at terminal L, passing to *o*, disc Q, contact point *k′*, spring *i*, hinge I, spring L, contact *f*, bracket M, post P, spring *a*, frame F, screw *e*, coils E E′, hinge J to terminal E. In this position the local cell contact between S and T is open.

In ringing, in reply, or to call attention, the current flows from terminal C to hinge K, post N, contact *g* (now closed by pressing the button O), spring L, hinge I, spring *i*, contact *k′*, disc L, to L and line.

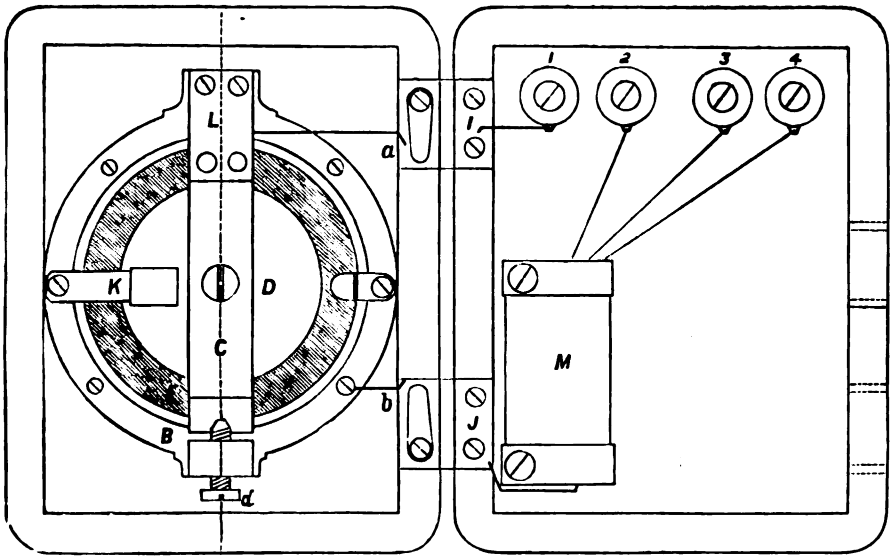

Fig. 22.

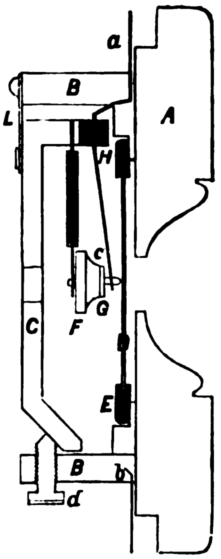

Fig. 23.

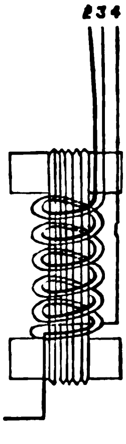

Fig. 21.

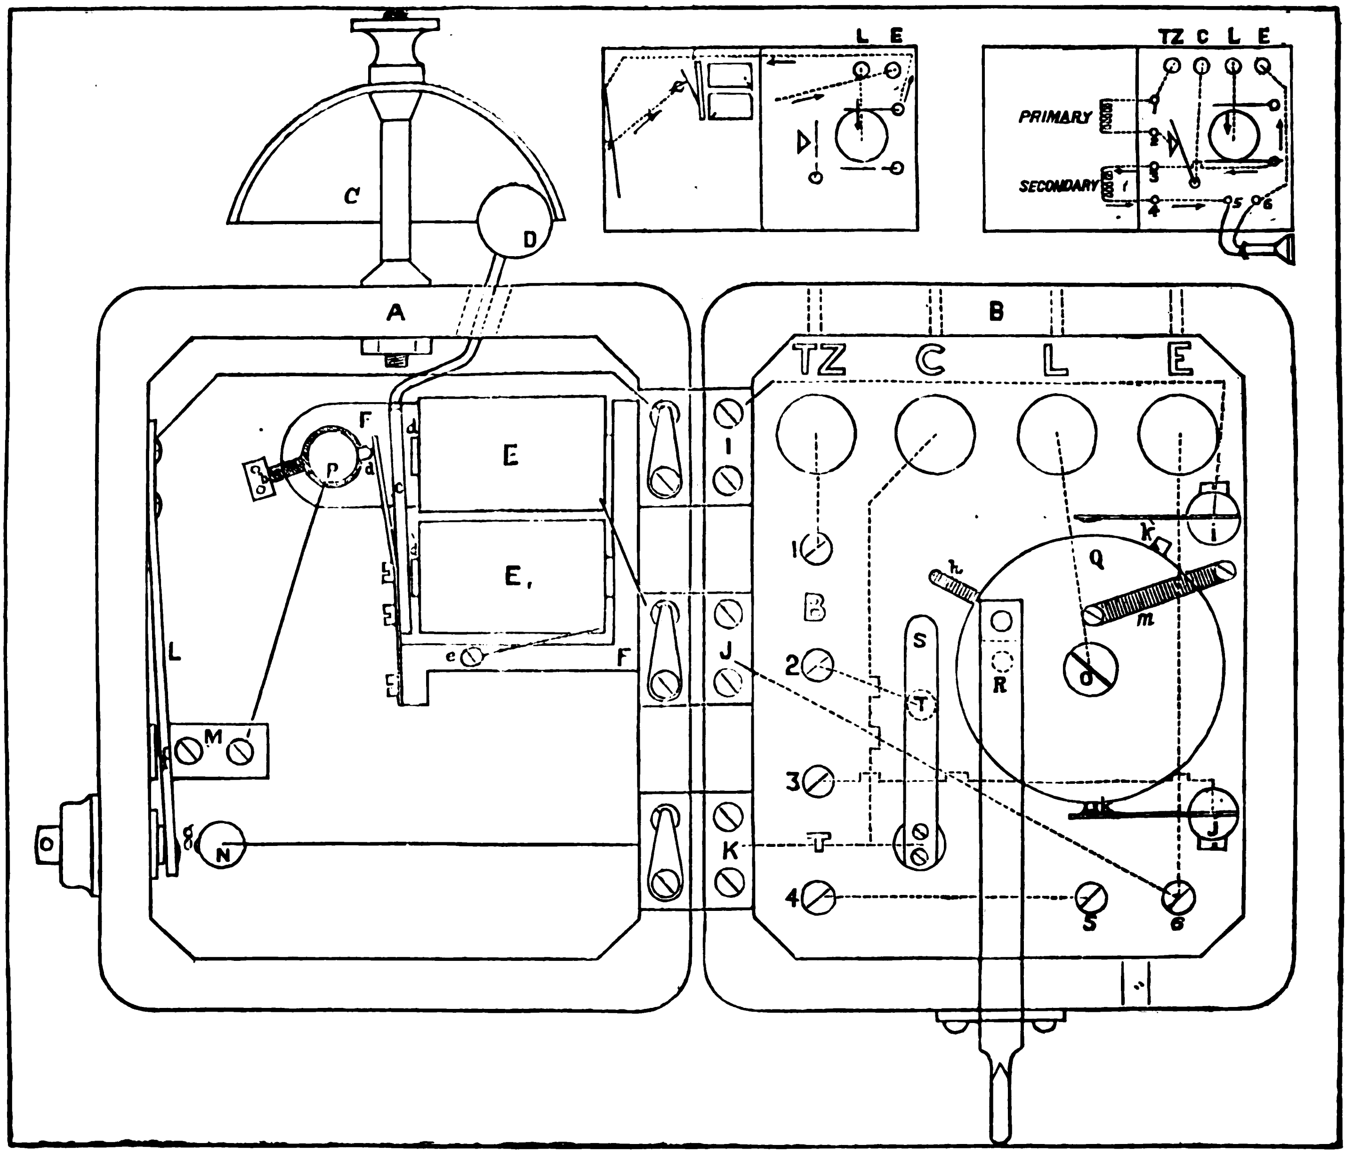

Fig. 25.

Digitized by Google

When the telephone is off the hook, the circuits are as follow: the local current flows from C to spring S to contact T (now closed), terminal 2 in transmitter, primary coil, iron frame, carbon button, platinum point to terminal 1 in transmitter, terminal 1 in switch bell to terminal T Z.

The telephone circuit is as follows:—Entering at L, screw *o*, disc Q, contact point K, spring *j*, terminal 3, terminal 3 in transmitter, secondary coil and terminal 4, terminal 4 in switch bell, terminal 5 to telephone, back through cord to terminal 6, thence to terminal E. The letters B and T stamped in the case refer to terminal 1 and 2 and 3 and 4 respectively, representing the local battery and telephone circuits.

In examining a switch bell see that none of the springs are loose, but held firmly by their screws; also see that the necessary contacts are firmly made. Put a little tallow under the spring where rubbed by the ivory pin *h*, but avoid getting any on the platinum contacts.

An improvement in the arrangement for closing the local circuit is now made which has a rubbing contact. The form shown on Fig. 25, being a dotting contact, often causes a fault by dust accumulating and particles of rust falling down from the contact with the ivory pin unless carefully greased. This new rubbing contact, however, unless very firmly made, acts as a microphone, sometimes causing an intolerable noise in the telephone. The slightest touch of sweet oil, however, cures this if the contact is well made.

Switch bells are now made and connected up so that the ringing key will act whether the telephone be on the hook or not. Some of these last-mentioned bells have two ringing keys fitted, one sending a positive, and one a negative current. When two subscribers are connected through the exchange, a polarised communicator is placed in a branch circuit of high resistance, so that subscribers may leave their instruments, and afterwards call each other up by pressing the white left-hand button. This signal passes the central office without dropping any signal plate. When the subscriber desires to be cut off, the right hand black button is pressed, which at once drops the signal at the central office.

MAGNETO SWITCH BELL.—The magneto bell, if well made, is very little liable to faults. The principal fault to which it is subject is in the working of the generator. This may result either from want of oil in the armature bearings or crank handle, or from defective gearing of the two wheels. The bell, when once adjusted, never fails, unless the inducing magnet becomes neutralised by lightning. The telephone hook sometimes works loose by the screw coming out which should hold it in position. This, however, is a mechanical fault that can easily be obviated in new instruments. The peculiar pattern of binding screw adopted by the Americans is particularly liable to work loose unless it is very tightly screwed up. This point should be carefully attended to. A brass screw eye should be placed just under the telephone cord terminal, the cord being passed through and tied in a knot; this prevents the strain coming on the attachment to the terminals. The switch bell is usually mounted on the top of a long back board, under it is placed a Blake transmitter, and at the bottom the box containing the local cell, the top of the box forming a sloping writing desk. The connections for these bells will not be given here, the forms being so various, and instructions are issued by each manufacturer.

(TO BE CONTINUED.)

THE DEVELOPMENT OF ELECTRIC LIGHTING.*

BY J. E. H. GORDON, B.A.,

Manager of the Electric Light Department of the Telegraph Construction and Maintenance Company.

Among all the great industries which in this wonderful last fifty years have been developed, there is none, perhaps, that has had so stormy a birth as the industry which we have met to speak of to-night, namely, that of electric lighting. We must remember that the public know very little indeed about electricity, in fact, nothing. Even in the early days of railways, although there was much ignorance about steam, still everybody had seen a kettle boiling, and had some vague idea of what steam might be even if he did not know what it could do. But the public do not know what electricity is, nor have they any knowledge of its laws; therefore, at one time, they were ready to believe any statements made to them about electricity. Nothing was too extravagant, too startling, or too ridiculous for the public to believe in the early days of electrical enterprise. We all remember that panic in gas shares which occurred about three years ago, when numbers of the public rushed to their brokers, and directed them to sell their gas shares at any sacrifice, to throw them away if there was any liability on them even, but to get rid of them. Why? Because a telegram had come across the Atlantic that Mr. Edison said he had made a discovery which would supersede gas. Few remember that, even with the most perfect discovery, it would at least take a little time to provide for an industry involving a re-investment of capital in England alone of about £100,000,000 sterling, for that is about the amount invested in gas. They imagined this great change was coming instantly. However, this change did not come instantly. Then they said Mr. Edison was an imposter, and that the electric light was a failure, because it was found that we could not undertake to supply one hundred lights when the whole plant was made for the supply of one hundred lights only, at the same rate as one hundred gas lights when they form part of a system supplying, perhaps, one million.

You must not for a moment think that Mr. Edison was to blame for this. Mr. Edison is a genius, and one of the greatest inventors of the age, and he has, in a very high degree, that poetic and prophetic insight which is able to see beyond the trammels of difficulty, and to know in his own mind, for certain, what will come in the future. He saw that the thing could be done, and said so. And, further—it is, perhaps, a failing of inventors, and being an inventor myself I may say it—Mr. Edison, like all inventors, has that enthusiastic imaginative temperament which is necessary for the development of inventive skill, and possibly he may sometimes have slightly confused what he was certain shortly would be done with what had already been done.

Now, this development of electric lighting has suffered to some extent from its enemies, but of course it is understood that gas shareholders are its natural enemies, and will do all they can to retard it; it is perfectly fair and right they should do so. We regard them as fair and open enemies; we are quite willing to fight them on their own ground, and hope the best man will win. But they have not done us much harm—in fact they have done us good. If there had been no other light to fight against, electric lighting would not have developed as fast as it has done. But electric lighting has suffered terribly, not so much from its enemies as from pretended friends. It has suffered much from the operations of persons who, while professing to be interested in electric lighting, and to desire to hasten its adoption, have only been interested in the progress of Stock Exchange operations, and the formation of bubble companies.

Whenever any industry is started which is at all new this will always occur, and the extent to which it occurs is measured, to a certain degree by the credulity, and more by the ignorance, of the public. If companies are brought out in connection with a subject the public know all about, there is not much chance for the public to be deceived, but if it is a subject they know little about, they are easily deceived, and when you come to a subject like electricity, about which the public know nothing, there are special opportunities for the speculator. I hope the ground is now cleared, and that these bubble companies, having satisfied their promoters, are disappearing, and making way for honest, legitimate enterprise to go on.

Now, to turn to the more practical and the more important part of our subject, we have to think what is the problem which has to be solved in the establishment of electric lighting; it is first to provide a perfectly steady, perfectly safe and reliable light, and what is very important still, but which is second, to provide that light cheaply. It is no use getting a light a little cheaper than another, if it is to go out or to blink. Our first consideration must be to make the light perfect, the second, following closely, but still second, must be to make it cheap. This problem must be regarded as a whole, I mean the problem of making it perfect. It has been attacked too much in detail, and the reason of that is that, for success in electric lighting, the knowledge of several branches of science is required, which are not often united in the same person; an electrician, for instance, is very often not a first-class engineer. It is no use getting a little more out of your dynamo if that dynamo will not fit the engine; if you have a certain dynamo that works conveniently with your engine, it is no use making the dynamo one or two per cent. better if the alteration causes you to lose 10 per cent. more in transmitting power to it. You must regard the engines, dynamos, mains, &c., all as one complete system, and you must remember that if anything goes wrong the electric lamps will not make excuses like we may make in the laboratory. They will not say it was not the dynamo's fault, but it was the engine's fault, or the boiler's fault. All that the public would be concerned with was that on this or that occasion the light went out. Therefore we must not despise anything, however foreign it seems to our subject, if it will help to make the system, regarded as a whole, perfect. The electrician knows very well that the principle of a dynamo is to move a coil of wire through a magnetic field, and he is very apt, when he is a pure electrician, to think that he has invented a wonderful dynamo if he gets a coil of wire that will

* A Paper read before the Society of Arts.

FREE LIBRARY OF THE UNIVERSITY CALIFORNIA
Digitized by Google

go through a magnetic field. He says here is a magnet, and here is a coil of wire, the coil is to be thin and the magnet strong, and the magnet is to be moved fast through that field. Then some outsider says, "How are you going to secure it, and attach it, and support it?" "Oh," he says, "any practical man can tell you that;" but I am afraid that when "any practical man" has found out that, he is apt to patent it and keep it to himself, and sometimes he says that what the electrician has given him is the very smallest part of the invention. Perfecting dynamos is an engineering problem, quite as much or more than an electrical problem.

We must not spend time in going into the details of electric machines, but there are one or two points I may be pardoned for alluding to. It is bad policy to cheapen your system by endeavouring to greatly cheapen the dynamo. The contract price to be paid by a company for electric lighting plant will be one sum for engines, boilers, dynamos, mains, buildings, &c., and it does not matter if the dynamos are a little cheaper, and the engines dearer, so long as the total sum remains the same. But whatever else we economise in, we must not economise in the dynamo; for this reason, that the cost of the dynamo is comparatively a small fraction of the cost of the plant, but the dynamo is the very vital heart and lungs of the whole affair. If anything is wrong with the dynamo, it is no use having the most perfect engines and the most perfect lamps, the lights will go out. Therefore, the dynamos must be perfect, and any economy, any extreme cheapness that is required, must be achieved in some other part of the plant.

Now, this question brings us to a controversy which has been going on, and has been universally discussed ever since electric lighting was first heard of, and which I think will continue to go on for some time, that is, the controversy between the relative merits of high speed and low-speed dynamos. It is necessary in a dynamo that the coil of armature wire should pass at a certain speed through the magnetic field, and that speed can be obtained in two ways; the wire is wound upon a wheel, and you can either have a small wheel which revolves many times a minute, or a big wheel revolving few times a minute, and you get the same speed of the rim in each case. The controversy between high and low-speed dynamos means this: Will you have a small wheel revolving very fast, or a big wheel, revolving very slowly? The first and natural opinion is have a small wheel revolving fast, for you can make the dynamo a good deal cheaper that way; it takes up less space, and altogether seems more convenient. I think every one when he begins electric lighting works approves of high-speed machines. I did myself at one time, very strongly; in fact, less than two years ago, I wrote an article in the *Quarterly Review*, in which, if I recollect rightly, I said the dynamos of the future "will, we believe, revolve much more rapidly than at present; their speed will only be limited by their tendency to fly to pieces." Then my friends and I set to work to build a dynamo on the principles I had laid down in the *Quarterly Review* article. We soon found that in a large, high-speed machine there was a great deal of difficulty in getting the power into it at all. You had to put belts to it, in fact a number of belts and counter-shafts, and there was always a good deal of slipping. Then the belts going at high speed used to make a most terrible noise; there was a deafening roar in the dynamo room, and the whole building used to shake. All these things were bad in themselves, but they were worse in this respect, that all these vibrations, whether of air forming sound, or of the building itself, required mechanical force to produce them, and every bit of that force was stolen from the steam-engine, and taken away from the force that ought to be used in producing light. I suppose this ought to have convinced me that high-speed machines were wrong, but it did not. We went on, we tried a machine, it worked very nicely indeed for an hour, and we got excellent electric results, and were very pleased. Then certain vibrations began to get worse, and I thought it advisable to send the workmen away. There was one safe spot where the person attending the machine was able to stand, from which I was able to watch what happened. The experiment was conducted in a cellar at Wharf-road, all vaulted with brickwork backed by the earth of the street, and it was so hard that when, on some occasion, we wanted to put a spike into it, we were unable to penetrate it at all. After a few hours' work the dynamo flew to pieces with a loud explosion, and I have here some of the few fragments that were left of it. Here you can see the fracture of a massive piece of iron that was caught by it; here are portions of the holders of the revolving magnets. I have not much of it here, the rest of it was picked up in a shovel. The only large piece which was found was a piece which weighed 1½ cwt., which struck the hard wall of the cellar (the distance from the dynamo being about 25ft.), and it cut a hole 2ft. in diameter, and 2ft. deep. Another piece skimmed along the vaulted roof, and made a series of grooves in which you could put your two fists. After that experiment we thought we had had nearly enough of high-speed dynamos—in fact, we thought we had nearly enough of dynamos altogether. Here, perhaps, although it hardly belongs properly to the subject of the paper, I must ask your indulgence if I turn aside for a moment to say a few words of tribute to those friends who, both by their moral and material support, helped me through that very difficult time. After this explosion, when it might have been fairly thought the whole attempt was at an end, my friends met almost among the ruins of the dynamo, and in a few days they subscribed a large sum of money, and said to me, "Go on; build us another dynamo ten times as large as the first, only," they said, "make it strong enough this time." We set to work and built a second machine, and this time we went on very different lines. We made the wheel enormous, and made it run very slowly, taking good care that the whole thing was strong enough. The first machines had taken two to two and a half years to make, the second machine took about eight months, and this was last year, and the experiments cost a great deal of money; one thousand pounds went after another, and still there was no result. Things seemed far from completion, and the money which had been handed to me to build the machine was spent three times over before the machine was finished; still my friends said "Go on, if it costs three times as much as you expected, you must make it do three times as much work." At last we were all ready to try the experiment, and for the last week or ten days I may say we had given up going to bed; it was no use, for we could not sleep; we used to go to bed for two or three hours, but we spent nearly all night in the factory. At last my friend, Mr. Clifford, the Telegraph Construction Company's chief engineer, and myself, began the final trial; we began on the Saturday morning, and thought we should be ready to start the engines on Saturday night; we got the steam up, but first one hitch occurred, and then another, before we could start, and at last it was three o'clock on Sunday morning before we made our first trial. That failed completely; the machine did nothing. We looked over it, and saw what was possibly the cause of error, and set to work to change the connections. Now, if you are changing connections in little dynamos, it is simply a matter of unscrewing two or three screws, and changing the wires, but with this large machine it was not so simple; it took as many men as could cluster over it until six o'clock in the morning; then we got a little better result, and went home for a few hours sleep. We started again early on Monday morning, and at nine o'clock on the Monday evening we were ready for the trial. The experiments were made at the Telegraph Construction Company's Works, at Greenwich, works which are about a third of a mile long, and cover 14 acres; there are 1,200 or 1,400 lights all over the works, and, as the cable department was then busy, there were about 1,000 men at work, and a little glimmering gaslight over each lathe. When I turned the valve the whole place burst into a blaze of daylight at once, and we felt at last rewarded for that three years of anxiety we had had before.

Now, what are the chief advantages of a big machine as compared with a small one. I think the chief advantage of all is that we can dispense with belts. With a big machine we get the necessary velocity by the largeness of the wheel, and, therefore, can cause it to revolve only the number of times in a minute which is not too great for the steam engine to revolve, and can connect direct to the steam engine. Mr. Edison was the first to point out the importance of this, and his was the first very large machine which was made. He has constructed a very large dynamo, which works 1,300 of his lamps, equal to about 1,000 20-candle lamps, his being 16-candle. It has been worked extremely successfully in New York, and also in Holborn; and I will now throw on the screen a picture of it. Then I will show you some of the important points, not of dynamos generally, but of a large machine as compared to a small one. You know that a dynamo machine consists of some apparatus for causing a coil of wire to revolve opposite a magnetic pole, or else magnetic poles to revolve past a coil of wire. In the one you see before you the shaft is geared direct to the steam engine, no belting at all being required. It is driven at the speed of 350 revolutions a minute.

I now come to a very important point, which is, where the current is taken off. Of course, if a current has to be taken from a moving coil to fixed wires, such as the conductors that go to the streets, there must be sliding or rubbing contact of some sort; and you have all seen in ordinary dynamos the contact brush or commutator, and there is always a little sparking. As the current gets greater that sparking gets greater—not proportionately, but still it is greater when you get a large machine. I must say, myself, I think the current for 1,000 or 2,000 lights is about the biggest that can be taken off by rubbing contact; but I never heard that with this 1,300-light machine there has been any difficulty with this. Still, as a matter of prudence, I should not consider it advisable to take enormous currents through rubbing contacts. I am speaking of currents which will supply

Digitized by Google

as many lamps as come from our big gas works, therefore when we designed this machine I have been speaking of we arranged it somewhat differently. We used an arrangement which is not new, but was never applied on a large scale before, namely, causing the magnets to revolve and the coils to be fixed. That enables the current, however great, to be taken off without sparking at all, there being a metallic connection the whole way from the fixed coils to the mains.

Here is a diagram of our own machine. This machine has been worked up to nearly 2,000 lights, and we were able to get this off a fraction of the coils, and we have no doubt it will give about 5,000 lights with adequate engine power. We call these 5,000 lights the baby ones. There will be much bigger ones made some day, we hope. There are 32 magnets, which revolve between fixed coils, whence the current is taken off. I must be pardoned in my illustration of big machines for going so much into the details of my own, and so little into the details of the excellent machines of Mr. Edison. My excuse must be, first of all, I am not so well acquainted with the details of Mr. Edison's as with my own; and, secondly, from the natural feeling a parent has for his own child, for he always believes it to be the finest child in the world.

We now come to a requirement which is common to all large machines—namely, a method of adjusting and regulating them while they are going. You see we have to keep the pressure constant, and we have a varying demand. We put on a number of lights when we start, and then somebody turns out a number of lights. Later on somebody else turns a number on, and we have to keep the pressure absolutely constant. Now, with any machine, such as this, if a thousand lights say are on, and another 500 are put on, the pressure will drop, and the 1,500 lights would not be in proportion so bright as the former 1,000. Similarly, if 500 are taken off, the remaining ones would get brighter and break the lamps, and therefore means for compensating for these changes have to be provided. The way in which the regulation is done is by varying the strength of the field magnets. These magnets, which are fixed on the big revolving wheel, are not permanent magnets, but are magnetised by the current of a small direct current machine. At present we use a very good little machine made by Mr. Crompton. This small direct current machine is driven by a small separate steam-engine, and by varying the speed of this small steam-engine, we can vary the strength of the current in the magnets, and so we can alter the pressure just as we want it. Of course we have to alter the pressure according to the requirements of the district, and this is the way the regulation is at present done. The picture on the screen represents the regulating room of our works at Greenwich. First of all we have to see what pressure is right, and for that purpose we employ a photometer, an iron rod which casts two shadows on a screen, one the shadow from a candle and the other the shadow from an electric light further back, the relative distances being so adjusted that the candle-power of the lamp is correct at the moment that the two shadows are equal. By shifting the position of the candles we can work to any candle-power we prefer. The lamp employed being a fair sample lamp, we know that if that lamp is right all the others are right, but we have one or two connected from different parts of the factory, which can be turned on by means of switches. Now, suppose some one at the other end of the factory turns off 100 lights, when there are a large number on, that would not be perceptible in the factory, but the man here can see the change of brightness much more readily than any one can in the open room or yard, and he at once sees that the pressure has run up a little bit. He then turns this valve a little, which partly shuts the tap and diminishes the supply of steam to the small engine, that diminishes the speed and the strength of the magnets, and so takes the pressure down as required. Similarly if 100 lamps are put on he finds the brightness drops, and he has to open the valve, and make his small engine run faster. There is one very important feature which it has been necessary to put into this regulating apparatus, and that is due to the property of the human eye to accommodate itself gradually to changes of light. The pupil of the eye expands and contracts, and takes in pretty nearly the same quantity of light, if the illumination is within certain limits. Although the eye is very sensitive to sudden changes of light, yet if you make the change sufficiently slowly

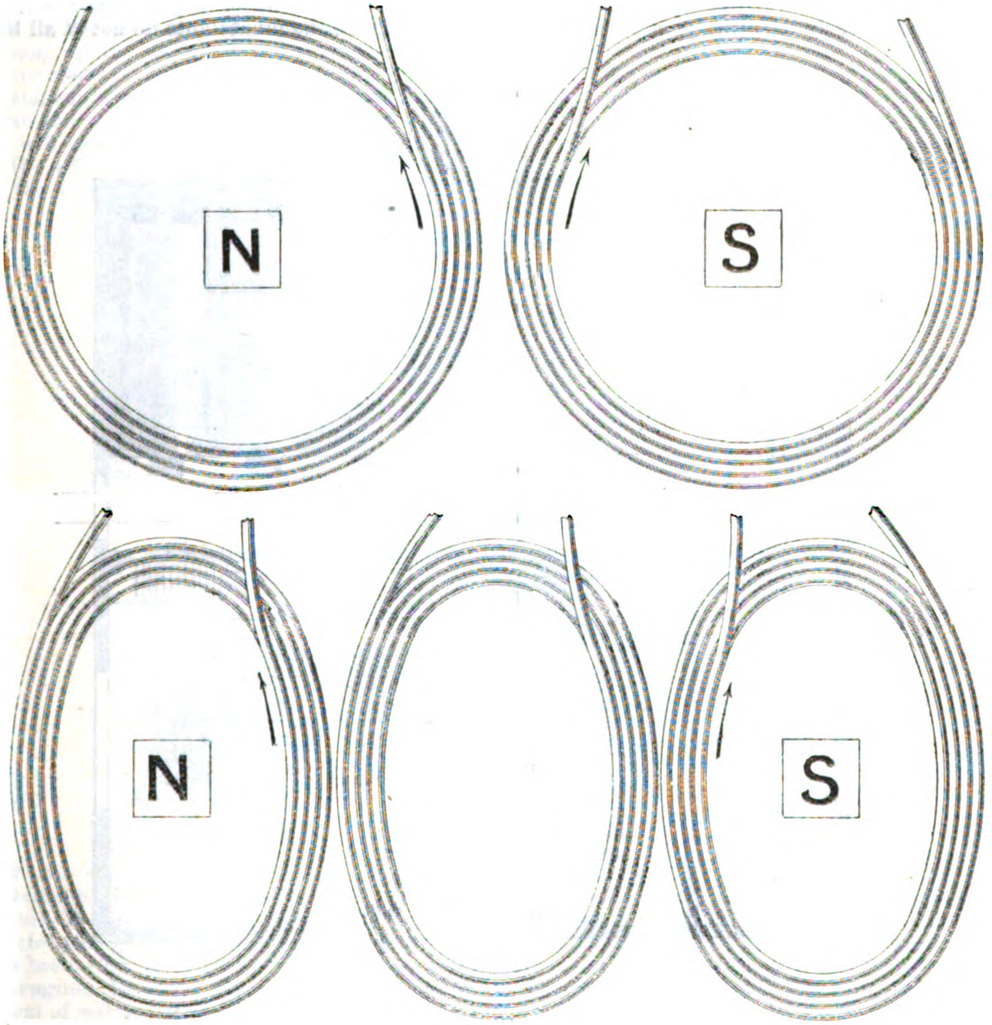

Fig. 1.

Digitized by Google

you allow the pupil time to expand or contract, and the change is not noticed very well. Therefore, instead of turning this valve rapidly, it is turned by a slow screw, so that it takes at least a minute to make a change of light equal to one candle-power. The result is that, even if a considerable change has to be made, such a change is never noticed at all. At the back of the room there is a steam-pressure gauge, showing the pressure on the boiler, and an indicator showing the speed of the large engine, and two men stand here on duty in turns all night to work the valve.

You may say that this is an expensive way of regulation, on account of the cost of men's wages; but what we have to consider in the commercial aspect of electric lighting is not the price of working each machine, but the price of working each lamp. It would have been ruinously expensive to have one or two men to attend to a small machine, but when their wages are distributed between 5,000 or 15,000 lamps, it becomes a very small item of expense indeed, although those same wages distributed between 500 or 1,000 would be very extravagant.

There is one small point about this machine, before we leave the technical part of the subject, which I may be pardoned for mentioning; although it is a purely scientific point, I think it is two opposite currents, and we only got the difference between the actual current induced by the magnet, and the back current induced by the next coil. The practical result was that the efficient lighting we got out of the machine was reduced to about one-half. To get over the difficulty, we arranged the machine as shown in the diagram below; we made a number of fixed coils, twice the number of the magnetic poles, flattened them, and squeezed them together, so that each pair of coils was acted on alternately, and between each there was a coil which was not in use at the moment; therefore, although there was a tendency to induce back currents, yet each pair of active coils being separated by an intervening coil, the action was so small as not to be perceptible, and thus the quantity of electricity we could get out of the machines was nearly doubled. We hoped we had now got the dynamo perfect, and that we had solved the problem, and got to the end of our troubles. We had got the dynamo as perfect as we knew how, but we found our troubles only beginning. It is a small portion of the problem of electric lighting to get the dynamo perfect, because there are so many details to be attended to. In putting up a plant for 10,000 lights in the middle of a populous town, a town of wealthy houses, where the inhabitants do not at all like smoke and waste

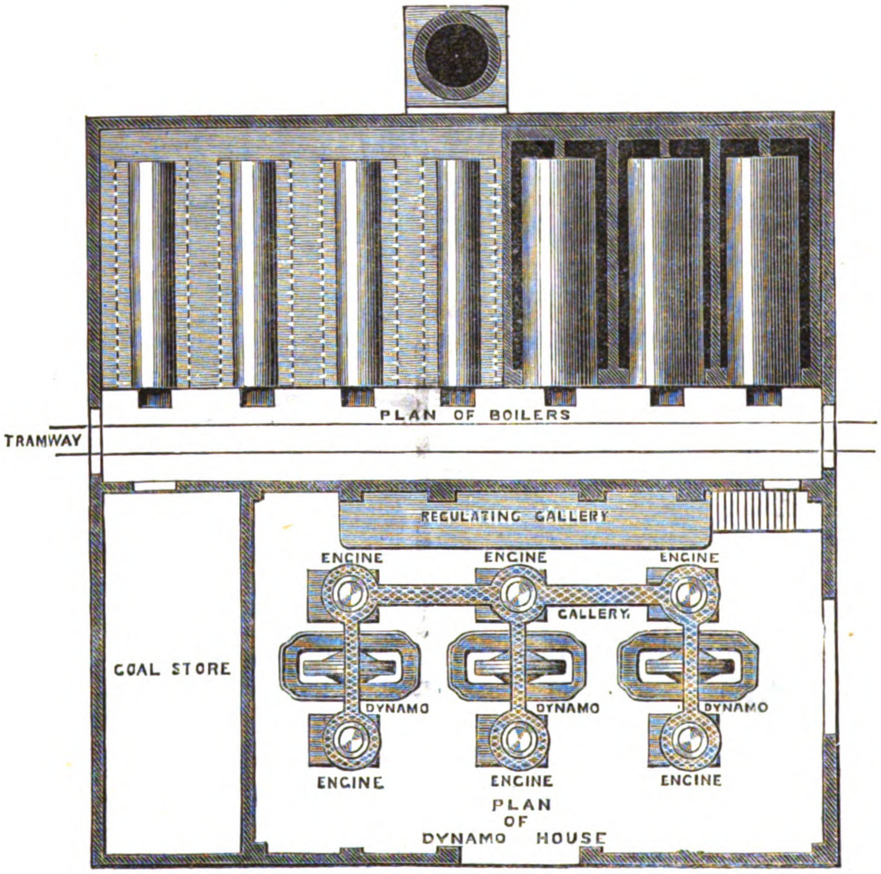

FIG. 2.

of some general interest as showing the kind of difficulties which the designer of any new engineering work has to encounter. In our first model machine we made the same number of coils as there were magnets; that is to say, there were a series of round bobbins in that disc of the machine, and a similar number on the revolving wheel, and currents were induced in the way usual in that class of machine; in fact, the arrangement was something as shown in the upper part of the diagram (Fig 1.) The two centres marked N and S represent the two poles of neighbouring magnets, and these coils represent the coils of wire acted upon by them as they pass, the direction of the currents being the direction shown by the arrows, one going each way. On the first experiment we put one coil on the small experimental machine, and got a good result, but when we put on the next coil alongside we found the mutual action of the two coils pulled down the amount of light produced nearly 50 per cent.; in fact, diminished the power of the machine nearly one-half. A little study of the laws of induction will show you how that occurred. It is a well-known law that a varying current, under certain circumstances, will induce a current in an opposite direction to itself. Here was a current travelling in one direction, which induced a current in the opposite direction, in a neighbouring coil, so that we got steam, there are a great many matters to be attended to. On diagram (Fig. 2) I have shown a plant for an installation for 10,000 lights, which we hope to have the opportunity of putting up soon. This is not the only way, perhaps, not the best way in which it could be worked out, but it is one way which has commended itself to us. There is the plant, an end elevation, and an elevation of the boiler house. Of course, we have to get our boilers in pretty close, there are seven boilers here. Then there is the dynamo house with three dynamos (Fig. 3), each working 5,000 lights, two to be always at work, and one in reserve, the whole plant being designed for 10,000. Then we have an arrangement so that the mains are laid double. That is to say, each house has half its lights from one dynamo and half from another, so that supposing an earthquake upset one of the dynamos and put it wrong, then only half the lights would go out; the town would not be put in darkness. There is one class of accident which may occur to any machine, and it is, I think, about the only difficulty which large dynamos are liable to—that is, getting a hot bearing. But an engine driver is not worth his wages if he cannot keep an engine with a hot bearing going for a quarter of an hour, and supposing he finds he has a hot bearing, all he has to do is to start the spare dynamo, get the

Digitized by Google

speed of that the same as the speed on the other, start the exciting engines, get the pressures constant, then pull over the switch, and all that will happen will be a slight jump in the light, and then the engineer may instantly stop the heated dynamo, and attend to the bearing. The engines are condensing engines, each dynamo to have two, and they will require about 510 indicated horse-power when at full work. Each engine is calculated to have a power of 275 indicated horse-power, so as to give about 550 horse-power available, which is sufficient reserve. Again, there are boilers in reserve; 4½ boilers would give sufficient power, so that there will be always two boilers standing quite idle which can be cleaned. There is a large crane running along the roof, which we used to put the machinery into its place, and to lift any part of it as may be required for repairs.

I have spoken of condensing-engines, and I think we must have condensing-engines, at least, in all important and wealthy towns. There are certain advantages of enconomy which are matters quite open to discussion, but I think they are more economical even in London, where water is expensive. We have seen lots of engines for small electric light plants which are not condensing, which do very well, but they have all been small. If you only want 10 or 20, 50 or even 100 horse-power, you may send the waste steam up the chimney, it disappears in the air and you hear no more about it, but if you have over 1,000 horse-power even in this station, which is regarded as a small experimental one, and send the waste steam into the air, two or three unpleasant things will happen. First, you will choke the chimney, because the effect of the steam will be to cake the soot, and so spoil the draught, and some day you would find the furnace would not draw; secondly, that steam would attract all the London blacks and form a fog to which our present fogs would be as nothing, and that would be a bad introduction of the electric light, one of the great arguments in favour of which has been that it is to keep our houses clean. With a condensing-engine, the waste steam is all condensed and goes away in the form of water. It is a hard saying to say there must be condensing-engines, because condensing-engines very greatly increase the first cost, but in spite of this I say we must make up our minds that, if we have the electric light at all, we must be prepared to pay for condensing-engines. We must remember too that there is a special clause in the Electric Lighting Act, and in the draft provisional orders, pointing out that no parliamentary powers conferred on a corporate or other body are in any way to be regarded as a protection to them against being indicted for a nuisance if they should cause one. Therefore we must arrange the plant so as not to cause a nuisance. With electricity there is more loss in transmitting it to a long distance than with gas, so that we cannot place our electric lighting machines at a great distance from the town. About half a mile radius is a convenient distance, and therefore the stations must be tolerably central.

As to the space required, these engine houses, for a 10,000 light plant, require 72ft. square; that is to say, two strips, 72ft. by 36ft. If it were more convenient for the site, we might set the boiler house end to end with the engine house. Then we have to get a supply of coals. We cannot put the coals on with a shovel when working on this scale. We have to think of bringing the coals in through a populous neighbourhood, storing them so as not to cause a nuisance, and feeding them so as not to cause smoke, and also so as not to have an enormous staff of firemen, whose wages would run away with our profits. We may assume at once that we must have what are called mechanical stokers to the boilers; that is to say, that each furnace is fed, not by shovelling in coals, but by a little steam apparatus, by which the coal is discharged into a hopper and slowly screwed into the furnace. That has the advantage that it enables us to burn much cheaper coal than we could otherwise do. We have here a coal store, which will hold about three weeks' winter supply, so that we need only coal about once a fortnight, and we can do it at night. The floor of this coal store is higher than the level of the boilers. The coal waggons will stop outside, there is a small crane by which the sacks are all taken up, the coal is emptied into the store until it is full, and that is the only time the coal is lifted. Near the bottom of the coal store there is a trap-door, and the coal comes out, and is run into trucks running on a raised tramway, and is discharged by its own weight into the hoppers of the stokers. There is, again, a second underground tramway for removing the ashes, so that the coal requires no handling at all.

You may say this is all very pretty, it is a very nice dream for the future, but what is it going to cost? people are not going to buy electric light at two or three times the cost of gas. That is a very important question, and he would be a very bold man who would speak too strongly on the subject, but yet I think we may say not that electric lighting will be dearer than gas, but that it will be almost immediately cheaper. I believe that in the future it will be about two-thirds the price of gas, and I am quite certain that at present it can be supplied in London at the same price as gas, when supplied on a moderately large scale. I have worked out on the table given at end of article some estimates of the capital expenditure and the working cost for an electric lighting plant, and there is not much difficulty in getting out the total expenditure accurately. The doubtful point is what the revenue will be. The two columns show the expenditure of capital and the annual expenses for electric lighting plant of two sizes, one for the supply of electricity to 60,000 lamps of 20-candle power, and the other to 10,000 lamps. In each case we can always count upon putting up half as many more lamps as we should supply, for never more than two-thirds of the total number would be alight at the same instant. First comes the capital expenditure—that is, the price which would be charged by the manufacturers for the whole plant—for machines, dynamos, mains, chimneys, and, in fact, bringing a pair of poles into every house, and starting the concern. Those are not estimated sums; they are taken from tenders which my company has actually furnished to corporations, so we know that the expenditure would not exceed those prices, because we have actually offered to contract to do it for the terms mentioned. The annual expenditure is another matter. It depends to a great extent on the number of hours per annum the lights are burning. I have spoken here of 2,000 hours, but I find there has been a good deal of misunderstanding about what is meant by that. I do not mean that all the lights will burn for 2,000 hours, but what I mean is that the average of the maximum number of lights burning at once will be about 2,000 hours. For instance, suppose in any particular house we put up 30 lamps; there are not, as a rule, more than 18 lamps

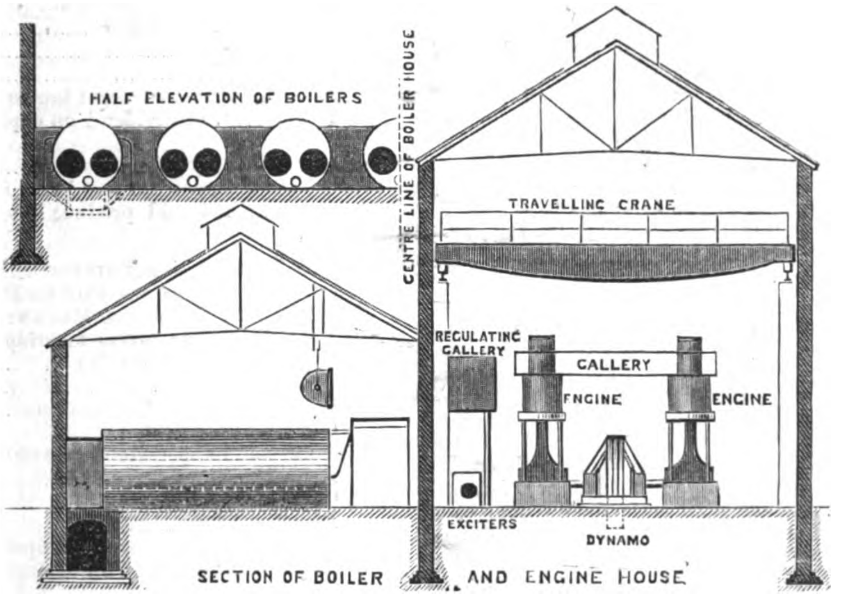

FIG. 3.

Digitized by Google

burning at once, and I should not call the expenditure of that house 30 times 2,000 hours, but only 18 times 2,000 hours. We need not provide, in plant, more than sufficient for the total number of lamps likely to be burning at once. I was talking to a gas engineer of very great experience the other day, and he thought I might count on never having more than half the lamps alight at once, but to be on the safe side I have taken it at two-thirds. The number of hours lamps burn depends on where they are. Street lamps burn nearly 4,000 hours; then come clubs, which burn over 2,000, but in private houses they would burn less. I think, with that reservation, that when we are speaking of the maximum number alight at once, and not of the maximum number put up, we may say that 2,000 hours is not very far wrong. Here is the way the expenditure is calculated. Every year put aside something for depreciation. Of course, the first year there would be nothing spent, and perhaps not for a few years, but some day new boilers will be required, and for that we should go on the reserve fund; therefore, each year a certain sum must be put aside for repairs. I have taken that at about £1,500—a certain per-centage on one part of the plant, and a different per-centage on another. It is a large per-centage on the boilers, a smaller per-centage on the dynamos, a smaller still on the mains, and a smaller still on the buildings. When the dynamos are run at a small speed, you can diminish the depreciation on dynamos and buildings; high-speed dynamos shake buildings to pieces before very long. Then comes slack coal at 11s. The consumption of coal has not been guessed at, but is taken by me from figures furnished by Mr. Hill, chief engineer at the Royal Mint. They have lately had a pair of engines, put up by Messrs. Maudsley and Field, of 500 horse-power, about the type of engine we think of using. They are not put up for electric lighting purposes, but for driving the machinery of the Mint; they have been working seven or eight months, and the figures for the consumption of coal are from the actual bills. By using mechanical stokers we can use slack coal at 11s., instead of steam coal at 18s. Mechanical stokers do not give us quite an advantage in the ratio of 11 to 18, because 1lb. of slack coal does not produce so much steam as 1lb. of good coal, but still there is a very great saving in using slack—about 13 to 18. The actual consumption at the Mint has been 2¼lb. of slack coal per indicated horse-power per hour. From that 11s., that item is taken of £1,230. Then there is the water for condensing purposes. Where we get waterside premises that will cost nothing, but in central stations we must reckon 6d. per 1,000 gallons, and a rough and ready rule is that the water costs about the same as the coal when you have to pay for it; and, therefore, I have to put it at the same price. Then oil is a small item, wages and superintendence includes the chief electrician, chief engineer, and various workmen required for small repairs. It does not include any large repairs, which are included in the first item. To be in the dark room, and attend to each engine and dynamo, requires three men always in attendance, *i.e.*, one engine driver, one labourer, and one man in the dark room; each of those works eight hours, so that you require three shifts of men. That makes a man's work 56 hours a week, 54 being the ordinary workman's time. They work, of course, seven days a week. Then there is rent and taxes, interest, directors' fees, and renewal of lamps. These must be renewed free of expense, that is the expense of renewing them must be included in the charge for electricity, whatever it is. I do not mean that if the glass of the lamp is broken it is to be renewed; but when a lamp has been destroyed by the current it is to be removed. When the lamp is broken by the current, the carbon alone breaks, not the glass, and the rule will be when the lamp has broken down, but the glass is intact, it can be exchanged without charge for a new one, but if the glass is broken, it follows it is broken by violence, and must be paid for. The total required revenue, including 10 per cent. dividend, you see is £14,928.

The light obtained from 10,000 20-candle lamps is the same as obtained from 14,000 14-candle lamps burning 5ft. of gas an hour, and they burning for 2,000 hours burn 140 million cubic feet of gas, which produces £15,000, which is the required revenue if gas is charged at 2s. 1¼d., the price in London being 3s. 2d. On the larger want the economy is great. The larger scale we work on the cheaper per lamp will the light be. The light, of course, will have to be supplied by meter, but about that I must postpone speaking to another time.

The introduction of electric lighting has, of course, been attended with many difficulties, but I do not think it has been attended with much more difficulty than must necessarily attend the introduction of any new industry requiring a great re-investment of capital. People who have capital invested in something paying well are shy of taking it out and putting it into something new. If you go to a corporation and say, "If you will spend £100,000 in electric lighting plant you will make a good profit," they will naturally say "That is all very well, but here is the money we are making from gas, and we prefer that;" and then they say, why do not you go in yourselves for this? If it is a good investment, invest your own capital in it, and show us practically it is so. I will not say that is not somewhat hard upon us, but, on the whole, it is a fair enough challenge, and we have made up our minds to accept it. I am not at liberty to say what arrangements are being made, but I hope I shall shortly be able to commence putting up in the West End of London such a plant as we have erected there, and we made an offer to a vestry, in a district in which we propose to put up the lighting, that we will guarantee that the maximum charge for a quantity of electricity equal to 1,000 feet of gas, shall never exceed 3s., and shall be reduced if we can do it. I will not enlarge any more on this, as it would savour very much of listening to a very vague scheme for you to listen to-day to what we propose to do, and it would savour somewhat of boasting for me to say it; but if this society would do me the honour, in about a year's time, to ask me to lecture before them again, then, if our work turns out as I hope and expect, I may be able to tell them not what we hope to do, but what we have actually accomplished.

PLANT TO SUPPLY ELECTRICITY SIMULTANEOUSLY TO 60,000 LAMPS OF 20 CANDLE-POWER EACH, EQUAL TO 85,000 OF 14 CANDLES. CAPITAL EXPENDITURE, £220,000.

Annual Expenditure, Lamps burning 2,000 hours per annum.

Depreciation and repairs	£8,000
Slack coal, at 11s.	7,100
Water, at 6d. per 1,000 gallons	7,100
Oil, &c.	850
Wages and superintendence (63 persons)...	5,390
Rent, rates, and taxes	1,000
Office expenses	500
Directors' fees	1,000
Renewal of incandescent lamps	12,000
10 per cent. of dividend on capital	22,000
Total required revenue	£64,940

85,000 14-candle gas burners burn, in 2,000 hours, 850,000,000 cubic feet, which would produce £65,000, at 1s. 6¼d. per 1,000 cubic feet.

PLANT TO SUPPLY ELECTRICITY SIMULTANEOUSLY TO 10,000 LAMPS OF 20 CANDLE-POWER EACH, EQUAL TO 14,000 OF 14 CANDLES. CAPITAL EXPENDITURE, £50,000.

Annual Expenditure, lamps burning 2,000 hours per annum.

Depreciation and repairs	£1,500
Slack coal, at 11s.	1,230
Water, at 6d. per 1,000 gallons	1,230
Oil, &c.	150
Wages and superintendence (30 persons) ...	2,968
Rent, rates, and taxes	250
Office expenses	250
Directors' fees	350
Renewal of incandescent lamps	2,000
10 per cent. dividend on capital	5,000
Total required revenue	£14,928

14,000 14-candle gas burners burn, in 2,000 hours, 140,000,000 cubic feet, which would produce £15,000 at 2s. 1¼d. per 1,000 cubic feet.

Gas in London is 3s. 2d. per 1,000 feet.

N.B.—It is not expected that each lamp erected will average 2,000 hours per annum, but that 2,000 hours is the average consumption of the maximum number alight at one time. Thus, if a house has thirty lamps, but not more than eighteen alight at once, the average consumption of that house will be 18 + 2,000 = 36,000 lamp hours per annum.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

(CONTINUED FROM PAGE 120.)

His discovery of the dual character of electricity was, like most of the other capital discoveries hitherto made, entirely due to chance. A piece of gold leaf having been repelled by an excited glass rod, Dufay pursued it with an excited rod of sealing wax, expecting that the effect would be the same. His astonishment, therefore, was great on seeing the gold leaf fly to the wax, and, on repeating the experiment, the same result invariably followed; the gold leaf, when repelled by glass, was attracted by resin, and, when repelled by resin, was attracted by glass. Hence

* The author reserves all rights of translation.

Digitized by Google

Dufay concluded that there were two distinct kinds of electricity, and, as one was produced from glass, and the other from resin, he distinguished them by the names *vitreous* and *resinous*.

In repeating Otto Guericke's experiments, Dufay discovered another general law, which enabled him to explain a number of observations that hitherto were obscure and puzzling. This law is, that an electrified body attracts those that are not so, and repels them as soon as they become electric by contact with itself. Thus, gold leaf is first attracted by the excited tube, and acquires an electricity by the contact, in consequence of which it is immediately repelled. Nor is it again attracted while it retains this electric quality; but, if now it chance to light on some other body, it straightway loses its electricity, and is then re-attracted by the tube, which, after having given it a new charge, repels it a second time, and so on, as long as the tube itself retains any electricity (Priestley's "Hist. of Elec.," pp. 40-50.)

The study of electricity was next taken up, in 1737, by Desaguliers, who, though born in France, in 1683, early removed to England, and died in London in 1744.* Two years before his death he published a "Dissertation Concerning Electricity," which is remarkable as being the first book on the subject in the English language. Desaguliers' investigations were mainly concerned with the relative conducting powers of various bodies, but he otherwise did good and useful work, by methodising the information that had already accumulated, and by improving in some important respects the nomenclature. Thus, the labours of Gray, Wheeler, Dufay, and himself, had shown that all matter was divisible into two great classes, these he now proposed to distinguish by the names *Electrics*, or bodies in which electricity could be excited by friction, and *Non-electrics*, or those in which it could not be excited, but which could receive it from an electric. He also first employed the words *Conductor* and *Non-conductor* in the same sense as they are used at the present day.

In the *Philosophical Transactions* for 1739, Vol. 41, p. 209, will be found his experiments on the transmission of electricity, which were made at H.R.H. the Prince of Wales's house at Cliefden, on April 15, 1738. "Having heard that electricity had been carried along a hempen string five or six hundred feet, but having only seen it done when the string was carried backwards and forwards in a room, by silk supporters, Dr. D. wished to try it with a packthread stretched out at full length; for which purpose, having joined a piece of cat-gut to one end of a string, he fastened it to a door; and having also tied another catgut to the other end of the string he fastened it at the other end of the house. At the places where the packthread was joined to the cat-gut he left 18 inches of the thread hanging down, and fastened a *lignum vitæ* handle of a burning glass to one, while he applied a rubbed tube to the other. He made the electricity run to the *lignum vitæ*, but with some difficulty, which he attributed to the sizing, being an animal substance, that still adhered to the thread, as it was new; therefore, he caused the thread to be wet with a sponge from one end to the other, to wash off the size; then was the electricity from the tube communicated very soon and very strongly; for the thread of trial was drawn by the *lignum vitæ* at the distance of a foot.

"Afterwards, having joined more packthread together, he made a string of 420ft. long, which he supported at intervals by pieces of cat-gut. The string was previously dipped in a pail of water, but great care was taken that the cat-gut should not be wet. Then he applied the rubbed tube at one end, while an assistant held the thread of trial near the handle at the other, whereupon it was strongly attracted, though the wind was very high, and blowed in the contrary direction to that in which the electricity ran.

"He first tried the experiment with the packthread dry, but then it would not succeed at that distance."—(Hutton's *Phil. Trans. Abridged*, Vol. 8, p. 357.)

* As a reason for his engaging in this pursuit so late in life, Desaguliers makes the curious assertion that he was debarred from doing so earlier by the peculiar temper of Stephen Gray, who would have abandoned the field entirely if he saw that anything was done in apparent opposition or rivalry to himself. (Brewster's "Edinburgh Encyclopaedia," *verbo* Electricity, page 415.)

It is difficult to reconcile this passage with the following, which we extract from Desaguliers' "Dissertation," page 47:—"Indeed, a few electrical experiments, made by Mr. Gray and myself many years ago, are mentioned in the first volume of my 'Course of Experimental Philosophy,' pages 17-21."

The following lines by the poet Cawthorn depict the neglect and indigence into which Desaguliers fell in his old age—

Can Britain * * * * * *
* * permit the weeping muse to tell
How poor neglected Desaguliers fell?
How he, who taught two gracious kings to view
All Boyle ennobled, and all Bacon knew,
Died in a cell, without a friend to save,
Without a guinea, and without a grave?
"The Vanity of Human Enjoyments."—V. 147-54.

Up to this time, and until some years later, experiments on the transmission of electricity to a distance excited no attention outside a very narrow circle of scientific men, and even amongst these, they served only to illustrate the two great electrical properties of bodies—conduction and insulation—without evoking the slightest suspicion of their practical value. The whole subject of electricity now, however, began to attract general attention, especially amongst the Germans, and the first consequence was considerable improvement in the power and efficiency of electrical apparatus. About 1741, Professors Hausen, of Leipsic, and Boze, of Wittemburg, revived the use of the glass globe machine, first introduced many years before, by Newton and Hauksbee, but which, after their time, had been supplanted, to the great detriment of the science, by the glass tube and silk rubber of Gray. Boze also added, for the first time, the prime conductor, which consisted of an oblong cylinder of tin or iron. This was at first held in position by a man, who was insulated, by standing on cakes of resin, but it was subsequently suspended by silken cords; and, in order to facilitate the passage of the electricity, a number of linen strings were added, which served the purpose, though very imperfectly, of the metal points now employed. Professor Winkler, of Leipsic, next substituted a fixed woollen cushion in place of the hand for exciting the globe, and lastly, in 1742, Gordon, a Scotch Benedictine monk, and Professor of Natural Philosophy at Erfurt, substituted a glass cylinder for the globe, and otherwise so increased the power of the machine, that he was able to kill small birds at the end of an iron wire 200 ells (250 yards) long (Priestley, "Hist. Elec.," pp. 64-67.

These various improvements were followed, in October, 1745, by the discovery of the Leyden Jar. This invention is one of the vexed questions of the science, being claimed, and perhaps with equal justice, for Von Kleist, dean of the Cathedral at Kamin, in Pomerania; for Musschenbröck, the celebrated professor of Leyden; and for Cuneus, a rich burgess of that town. Von Kleist appears to have been first, in point of priority of publication; but his account of the discovery was so obscurely worded, that it was impossible for some time to verify it. The following is an extract from his letter on the subject, which was addressed to Dr. Lieberkuhn, of Berlin, on the 4th November, 1745, and by him communicated to the Berlin Academy:—"When a nail, or a piece of thick brass wire, is put into a small apothecary's phial and electrified, remarkable effects follow; but the phial must be very dry or warm. I commonly rub it over beforehand with a finger on which I put some pounded chalk. If a little mercury, or a few drops of spirit of wine be put into it, the experiment succeeds the better. As soon as this phial and nail are removed from the electrifying glass, or the prime conductor to which it has been exposed is taken away, it throws out a pencil of flame so strong, that with this burning instrument in my hand I have taken above sixty steps in walking about my room. When it is electrified strongly, I can take it into another room, and there fire spirits of wine with it. If, whilst it is electrifying, I put my finger, or a piece of gold which I hold in my hand, to the nail, I receive a shock which stuns my arms and shoulders. A tin tube, or a man, placed upon electrics, is electrified much more strongly by this means than in the common way. When I present this phial and nail to a tin tube which I have, fifteen feet long, nothing but experience can make a person believe how strongly it is electrified. Two thin glasses have been broken by the shock. It appears to me very extraordinary that when this phial and nail are in contact with either conducting, or non-conducting matter, the strong shock does not follow. I have cemented it to wood, glass, sealing-wax, metal, &c., which I have electrified without any great effect. The human body, therefore, must contribute something to it. This opinion is confirmed by observing that, unless I hold the phial in my hand, I cannot fire spirits of wine with it."

In January, 1746, Cuneus made the same discovery, and, apparently, in the same accidental way. It having been observed by Musschenbröck and his colleagues, Cuneus and Allamand, that electrified bodies speedily lost their virtue, which was supposed to be abstracted by the air itself, and by vapour and effluvia suspended in it, they imagined that if they could surround them with any insulating substance, so as to exclude the contact of the atmosphere, they could communicate a more intense electrical power, and could preserve that power for a longer time.* Water appeared one of the most convenient recipients for the electrical influence, and glass the most effec-

* In a paper read before the Royal Society in 1735, Stephen Gray has these curiously prophetic words:—"Though these effects of the fire and explosion of electricity communicated to a metallic rod are at present only minute, it is probable that in time there may be found out *a way to collect a greater quantity of the electric fire*, and consequently to increase the force of that power, which by several of these experiments, if we are permitted to compare small things with great, seems to be of the same nature with that of thunder and lightning."—(Priestley, page 54.)

Digitized by Google

tual and easy insulating envelope. It appeared, therefore, very obvious, that water enclosed in a glass bottle must retain the electricity given to it, and that, by such means, a greater charge or accumulation of electric force might be obtained than by any expedient before resorted to. In the first experiments made in conformity with these views, no remarkable results were obtained. But it happened on one occasion that Cuneus held the glass bottle in his right hand, while the water contained in it communicated by a wire with the prime conductor of a powerful machine. When he considered that it had received a sufficient charge he applied his left hand to the wire to disengage it from the conductor. He was instantly struck with the convulsive shock which filled him with the utmost consternation, and made him let fall the flask. Musschenbröck and others quickly repeated the experiment, and with like results (pages 75—8. Priestley's "Hist. Elec.").

In describing these in a letter to Réaumur, Musschenbröck said he felt himself struck in the arms, shoulders, and breast, so that he lost his breath, and was two days before he recovered from the effects of the blow, and the terror. He added that he would not repeat the experiment for the whole kingdom of France. Boze, on the other hand, seems to have coveted electrical martyrdom, for he is said to have expressed a wish to die by the shock, (the name by which this phenomenon was known) that the account of his death might furnish an article for the Memoirs of the French Academy. Allamand, the associate of Musschenbröck, took the shock from a common beer glass, and lost the use of his breath for some minutes, and then felt so intense a pain along his right arm, that he feared permanent injury from it. Professor Winkler, on undergoing the experiment for the first time, suffered great convulsions, his blood was agitated, and fearing an ardent fever, he had recourse to cooling medicines. His wife, also, with a courage only equalled by her curiosity, twice subjected herself to the shock, and was so enfeebled thereby that she could hardly walk, and on trying it again, a week later, it gave her bleeding at the nose.* ("Priestley" pp 78-9)

An account of these extraordinary effects soon got abroad, and spread over Europe with the rapidity almost of the spark itself. The experiments were repeated everywhere, and excited the wonder of all classes towards what was regarded as "a prodigy of nature and philosophy." Indeed, so popular did they become, that great numbers of impromptu electricians wandered over every part of Europe, and enriched themselves by gratifying the universal curiosity at so much per shock.

But as soon as these first feelings of wonder had abated, philosophers set themselves seriously to study the powers of the new machine. The circumstances which influenced the force of the shock first engaged their attention.

Musschenbröck observed that if the glass were wet on the outer surface the success of the experiment was impaired. Dr. (afterwards Sir William) Watson, apothecary and physician, of London, next proved that, while the force of the shock was increased by diminishing the thickness of the glass, it was independent of the power of the machine by which the glass was charged.

By further repeating and varying the experiment, Watson found that the force of the charge depended on the extent of the external surface of the glass in contact with the hand of the operator; and it occurred to Dr. Bevis that the hand might be efficient merely as a conductor of electricity, and in that case the object might be more effectually and conveniently attained by coating the exterior of the phial with sheet lead or tinfoil. This expedient was completely successful; and the phial, so far as related to its external surface, assumed its present form.

Another important step in the improvement of the Leyden jar was also due to the suggestion of Dr. Bevis. It appeared that the force of the charge increased with the magnitude of the jar, but not in proportion to the quantity of water it contained. It was conjectured that it might depend on the extent of the surface of glass in contact with water; and that as water was considered to play the part merely of a conductor in the experiment, metal, which was a better conductor, would be at least equally effectual. Three phials were therefore procured and filled to the usual height with shot instead of water. A metallic communication was made between the shot contained in them respectively. The result was a charge of greatly augmented force. This was, in fact, the first electric battery.

Dr. Bevis now saw that the seat of the electric influence was the surface of contact of the metal† and the glass, and rightly inferred that the form of a bottle or jar was not, in any way, connected with the principle of the experiment. He, therefore, took a common pane of glass, and having coated the opposite faces with tin-foil, to within an inch of the edge, obtained as strong a charge from it as from a phial having the same extent of coated surface. Dr. Watson being informed of this, coated large jars, made of thin glass, on the inside and outside with silver leaf, extending nearly to the top of the jars, the effects of which fully corroborated the anticipations of Dr. Bevis, and established the principle that the force of the charge was proportional to the quantity of coated surface.—("Priestley," pp. 82-7.)

* It is no doubt to the "uncontrolled use of the imagination in science", that we must, in a great measure, attribute these first effects of an experiment with which electricians are now so familiar, and which every school boy and girl undergo nowadays from motives of curiosity or amusement.

† This question was very beautifully settled a year or two later by the celebrated Benjamin Franklin. He charged a jar, and then insulating it, removed the cork and the wire by which the electricity was conveyed from the machine to the inside of the jar. On examining these he found them free from electricity. He next carefully decanted the water from the charged jar into another insulated vessel. On examining this it was also found to be free from electricity. Other water in its natural state was now introduced into the charged jar to replace that which had been decanted, and on placing one hand on the outside coating, and the other in the water, he received the shock as forcibly as if no change had been made in the jar since it was first charged.—("Priestley," p. 144).

NOTES.

Honours to Mr. Swan.—In convocation at Durham, on June 26, the honorary degree of Master of Arts was conferred on Mr. J. W. Swan, the inventor of the Swan lamp.

West Coast of America Telegraph Company.—The coupons due on the 30th June next on the debentures of this company will be paid by Messrs. Barclay, Bevan, and Company. The coupons must be left three clear days for examination.

Electric Lighting at the Reform Club.—The electric light at this club, where the Elphinstone-Vincent machine is working Woodhouse and Rawson's lamps, has given so much satisfaction that the committee are now extending it to the billiard room.

Faure-Sellon-Volckmar Accumulators.—Mr. Emile Bürgin, the eminent electrician of Basle, has, by an arrangement with the Electrical Power Storage Company, secured the sole agency for the supply of the Faure-Sellon-Volckmar accumulators in Switzerland.

Illustrated Catalogue.—We have received the illustrated catalogue published by H. and E. J. Dale, of 26, Ludgate Hill, containing, besides the usual descriptions of electrical appliances, some special applications of electricity to the purposes of photography.

South Africa.—The Eastern Telegraph Company notify that the Eastern and South-African Telegraph Company's cable between Zanzibar and Mozambique became interrupted on Saturday afternoon. The company's repairing ship stationed at Zanzibar proceeded at once to restore communication.

Cochin China.—A despatch from Saigon announces that the Colonial Council has passed a resolution in favour of the construction of the telegraphic cable between Saigon and Haiphong, at the same time agreeing to bear the whole cost of the undertaking, provided that Tonquin and Cochin China remained united.

The Electric Light at the Fisheries Exhibition.—A great display of electric lighting will be witnessed at the garden party advertised to take place in the grounds of the Fisheries Exhibition this evening, and the arrangements for illuminating the buildings and grounds during the remainder of the exhibition are said to be now completed.

Caen.—The Caen Exhibition, opened on 5th June, and which will remain open until the 15th September, is illuminated in the evening by incandescence lamps, the current for which is supplied by an Edison dynamo, and also by a Berjot arc lamp, worked by a Méritens dynamo. Dupuy's electric locomotive, which unrolls and rolls up cloth to be bleached, is exhibited.

An Electric Rifle.—A rifle, invented by M. Clair, of Paris, is to be exhibited at Amsterdam, the powder charge of which is ignited at the front end by a platinum wire heated to redness by an electric current being passed through it, a simple "push" taking the place of both hammer and trigger. The current is supplied by an accumulator about the size of a good sized watch, placed in the stock or carried in the pocket. Two or more charges contained in the same barrel may be fired successively by employing platinum wires of different diameters, the smallest of course getting red hot first.

The Edison Exhibit at Vienna.—This exhibit will consist of three dynamo machines, one K, one L, and one Z. The K and L dynamos will be driven by an Armington and Sims engine. The Z machine will be driven by a separate 8 horse-power engine. Specimens of all the lamps made, and in fact, specimens of the various parts of the Edison system of lighting, will be exhibited. Part of the main building will be lighted by Edison lamps, as well as the "Restaurature," in Süd-West-Hof," some 175 metres from the machines. The fitting up of the exhibit will be under the supervision of Mr. F. Jehl.

Magnets.—In a short note on the carrying power of magnets in *La Nature*, June 23, a curve is shown as constructed by M. Séquard by means of the formula $p = a \sqrt[3]{w^2}$, where p = carrying power of magnet in kilogrammes, w = the weight of magnet also in kilogrammes, and a = a coefficient, which, for good steel, varies from 18 to 23. M. Séquard constructed his curve with $a = 20$. The conclusion of the note is that with magneto machines small coils should be exclusively used, and that in dynamos the coils moving in a magnetic field should be somewhat large.

The Dynamicables.—The idea, originating in Paris, of electricians meeting together for the purpose of dining and an evening's social intercourse has borne fruit in London, and a society under the name of the Dynamicables is gathering into its folds all those convivial spirits who like to meet and wyne. Each meeting has a new president, the principal function of the president being to nominate his successor. Each member has the pleasure of paying a half-guinea subscription per annum, and also of paying for his dinner. The next meeting of this social club will be held at the Fisheries Exhibition the first Friday in July.

Electric Lighting on Board ss. "Burmah."—The ss. "Burmah," 2,000 tons, built by J. Key and Sons, Kirkcaldy, has just been completed, and is fitted up with the electric light, Higgs's self-regulating dynamo being employed, and 70 incandescent lamps of 20 candle-power and 2 "arc" lamps of 2,000 candle-power are used. The trial is said to have proved a most decided success, and satisfaction was expressed on all sides, the extreme softness and steadiness of the light being commented upon. The work has been executed by The Electric Carbon Storage and Apparatus Manufacturing Company of Scotland (Limited), of Leith.

New Electric Safety Lamp.—M. A. H. Boullenot, *aîné*, chemist, writes from Issy-sur-Seine to the *Journal des Mines* that the Davy miners' lamp ought to be discarded now that there are Edison, Swan, and Maxim incandescence lamps in the market, only there is the difficulty of either fixing permanent conductors, or of dragging them about along with the lamp. He, M. Boullenot, has solved the problem of constructing a portable, self-contained incandescence lamp, which also gives warning of the presence of firedamp. He does not give particulars because his patents are not yet secured; but why does he not enter the lamp for Mr. Ellis Lever's £500 prize?

"Proceedings of the Royal Society of Edinburgh."—The number of the *Proceedings* just issued, viz., No. 112, contains comparatively few important papers on electrical subjects. We notice the following, "The Effect of Moisture on the Electric Discharge," by A. Macfarlane, M.A., D.Sc., and D. Rintoul, M.A.; "The Heats of Combinations of the

Digitized by Google

Metals with the Halogens," by Messrs. A. P. Laurie and C. J. Burton. This investigation is referred to in two papers, the first paper being simply preliminary, and was carried out with the "cuprous iodide cell." "On the Change in the Peltier Effect due to Variation in Temperature," by Mr. A. Campbell.

The Eastern Telegraph Company.—The Eastern Telegraph Company announce that, subject to the final audit, the accounts show, after placing £85,000 to reserve fund, a balance available for dividend sufficient to pay at the general meeting on 12th July next, the fixed dividend of 3s. per share, less income-tax, being at the rate of 6 per cent. per annum on the preference shares, and a final dividend of 2s. 6d., with a bonus of 1s. per share, both free of income-tax, on the ordinary shares, making, with previous payments on account, a total dividend of 6 per cent. on those shares for the year ended 31st March, 1883, and carrying forward a balance of about £2,790.

Time by Telegraph.—Under this heading the *Scientific American* mentions an improved method of synchronising clocks, and says: "The problem of correcting clocks throughout cities and towns by electricity has been heretofore supposed to be unattainable; by Mr. Hamblet's system, with a good clock at a central station, provided with the proper mechanism to send a single beat, not to exceed one second in duration, exactly at the beginning of each hour, and inexpensive clocks located in places within convenient reach of a local system of telegraph wires, a successful distribution of uniform time may easily and cheaply be maintained." We had thought the problem of correcting clocks by electricity was not exactly in the position herein mentioned, and that it was not only attainable, but had been and is done already by more than one system.

Photometry.—We are glad to see that Mr. Preece, F.R.S., has brought his proposed system of photometric measurement before the notice of the Royal Society. The standard of reference is a given surface illuminated to a given intensity, the light used being that of a small incandescent lamp. The amount of illumination is measured by the amount of current, the number of amperes giving the degree of illumination. The standard is a surface illuminated by a standard candle at 12·7 inches, or a French candle at a metre distance. We do not know who was the first to suggest the use of the electric current for photometrical purposes, we think the idea originated either from Mr. Preece or the late M. Schwendler. We might here say that to the best of our belief the method of ascertaining the distribution of the lines of force, as given in a note in p. 98, was first suggested by Mr. Preece.

Determining the Value of the Ohm.—By a recent Act of Congress, says the *Electrical World*, experiments will soon be in progress for determining exact values for several electrical constants. By the Act a committee of the recent electrical congress, consisting of Professor Rowland, of the Johns Hopkins University, Professor Trowbridge, of Harvard, and Professor Barker, of the University of Pennsylvania, has been authorised to undertake these experiments, and the work has been so apportioned that Professor Barker will determine the resistance of a given column of mercury. Professor Trowbridge will experiment on atmospheric electricity, and the most important feature, the determination in absolute measure of the standard of electrical resistance, the ohm, will fall to Professor Rowland, who will be assisted by Messrs. Kimball and Goodenow. The work will be done at Clifton, a suburb of Baltimore. It will begin in September, but the work of placing the necessary apparatus in position will go on during the summer.

The Future Electrical Engineer.—The electrical engineer of the future, says the *Mechanical World*, must have a sound practical training in the schools and shops, and more especially in the latter. He must be well grounded in the physical sciences and in mechanics, for he will have under his control complicated engines and machinery, and in their installation will have to be prepared for unexpected contingencies. He must be able to select the best engines and boilers for his purpose, to put them down, and design the best means for driving his machines; be prepared for breakdowns, with the best means for preventing and remedying them without calling in the advice of his brother the mechanical engineer. In hydrostatics and pneumatics, because of the analogies existing between these and electricity and magnetism. In sound, light, and heat, for a similar reason. In electricity and magnetism, in order that he may be acquainted with the basic theory of his profession, whatever it may happen to be at the moment. Besides all this, he must be a fair mathematician, and have a little more than a smattering of chemical knowledge.

Electricians in France.—On Thursday, June 21, was held at Durand's the fourth meeting of electricians of the society founded by the Comte d'Aros. It was decided (says *The Times*) by the meeting that a committee should be appointed to frame the articles of a new society for encouraging progress in electric science and corresponding with those in all countries who have made electric questions the chief object of their studies and efforts. This evening's banquet was presided over by M. Loewy, member of the institute, who had on either side of him M. de Lesseps, M. Faye, M. Robin, Admiral de la Gravière, M. Louis Figuier, and some 30 or 40 others, including 12 members of the institute, senators, deputies, journalists, and men bearing names well known in different branches of science. At the close of the dinner, between the toasts, M. de Lesseps announced a piece of news of importance. The president of the Suez Canal Company appealed to the members present to compete for a prize for the best means of lighting the canal by electricity. Without entering into details it is evident that such an innovation would very largely increase the capacity of the canal for traffic.

Electricity in a Rage.—The Philadelphia *Public Ledger* of May 26 says:—"During the thunderstorm on Monday night last, when the atmosphere was overcharged with electricity, a curious phenomenon occurred at Fourth and Arch streets. At that point the wires of the Reading Railroad Telegraph Company cross those of the Maxim Electric Light Company. In some manner unexplained, the wires of the two companies were brought in contact, resulting in the wires of both companies being completely burned through. The electricity then burned up two of the Maxim lamps, and rushing to the leading office on Fourth-street, destroyed several boxes and machines. During the same storm the wires of the Western Union and other companies being thoroughly wet, a current of electricity from the atmosphere straddled one of the wires and slid along to the switch-board in the office of the Western Union, setting it on fire and burning several instruments. Several of the wires burned completely through are in the possession of the police and fire alarm telegraph offices. For the time being several circuits were broken, but everything was soon placed in working order."

D'Or's Battery.—In answer to our request for information, a long advertisement from the *English Mechanic*, and

Digitized by Google

an extract from the correspondence columns of that paper have been kindly forwarded. We give the extract, which is as follows: "In answer to Albert Jenkin, inquiring about D'Or's battery, I can say it is a bichromate battery. The one I have ran down in three hours. It is his No. 2 battery. Here are the directions for charging it: Dissolve in a large wash jug 1lb. of bichromate of potash in nearly three quarts of boiling water, when cool add $\frac{3}{4}$lb. of commercial sulphuric acid, just giving one stir with a stick, and again allow to cool. This done, fill the jars to within $1\frac{1}{2}$in. of the tops. It has two carbons and one zinc to each cell. The carbons are $5\frac{1}{2}$in. by $2\frac{1}{4}$in.; the zinc $5\frac{3}{8}$in. by $2\frac{1}{8}$in., and $\frac{1}{4}$in. thick. There are three cells, and, of course, connected in series. It gave a light of about 1 c.-p. The method of raising the carbons and zincs out of the liquid is by means of two strings and a curtain-ring at ends of string, which, when raised, is hitched on to a screw outside of box." We have rather a strong feeling about this and similar advertisements, suspecting their tendency to mislead, but before commenting further we should like more information as to the No. 1 light.

Thunderstorms.—On the afternoon of Monday last a terrific thunderstorm burst over Chatham, and, unfortunately, caused the death of two persons, one of whom had taken shelter in a sentry-box at the Dockyard. At Cambridge, on the same day, the church of St. Botolph was struck, and some damage done. At Sturton, a cottage was struck; and various parts of Warwickshire, Leicestershire, and North Wales were visited by thunderstorms of unusual severity. At Stalybridge the Unitarian church was struck by lightning, which, igniting some birds' nests in the gutters, set the roof on fire. Two boys, who had taken shelter by a tree in the neighbourhood of Ashton-under-Lyne, were struck, one of them fatally. A similar case occurred at Lees, near Oldham, where a man was killed inside a hut which he had entered for refuge from the storm. On the previous day, Sunday, the Black Horse, at Rampton in Cambridgeshire, was set on fire by lightning and completely destroyed. The roof of a house in Huntingdon-street, Cambridge, was fired during the storm on Monday. In the afternoon of the same day a farm at Great Eversden was struck by lightning, and nearly the whole premises, together with some of the stock, were destroyed by fire. On Tuesday a house in course of erection at Kempton was partially demolished by lightning, which also killed a child in the same locality.

Overhead Telegraph Wires.—Mr. Fawcett, replying to Mr. Stuart-Wortley, in the House of Commons, on the 21st inst., said that, after careful consideration, he had come to the conclusion that it was beyond the province of the Post Office to inquire into the condition of overhead wires not belonging to the Post Office, unless they interfered with the working of the Post Office wires.—On Monday last Sir C. Dilke being interrogated on the same subject stated he had that day received a deputation from the vestries of the metropolis in conjunction with the Under-Secretary for the Home Department. The question had also been referred by the Home Office to the metropolitan vestries for information. There could be no doubt that in the city and in portions of Westminster there was a certain number of abandoned lines. The vestry of St. Mary, Newington, stated that if any such existed in their district, they would immediately take steps for their removal. The vestry of St. Giles made a statement which showed that in the opinion of some vestries ample power to deal with the subject existed in the present state of the law. They said that overhead telegraph and telephone wires had been stretched across the streets, but in all cases where the owners of abandoned wires had been ascertained the board had adopted steps to compel the removal of them, or, where they had permitted them to remain, to compel their being subjected to proper supervision.—Mr. Stuart-Wortley asked if those vestries which disputed their interest in the soil disputed their liability for injury?—Sir C. Dilke said the liability was in the person who erected the wires. The question of liability when no owner could be found had not yet arisen.

Legal.—In the House of Lords, on June 26, the case of Christopher *v.* the United Kingdom Electric Telegraph Company was heard by the Lord Chancellor, Lord Blackburn, and Lord FitzGerald. This was an appeal from a decision of the Court of Appeal, affirming a judgment of the Queen's Bench Division. Mr. Cottrell, Mr. Spalding, and Mr. Hunter appeared for the appellant; and Mr. J. G. De Witt for the respondents. The action in which the order appealed against was made was originally brought by one Thomas Allan, deceased, against the respondents in the Queen's Bench for the recovery of the sum of £20,000 for an alleged breach of agreement. The respondents, by their pleas, pleaded that before the action was brought the agreement relied upon had been rescinded. It appeared from the appellant's case that Mr. Allan, the original plaintiff, was a gentleman of great scientific turn of mind, and devoted himself to the development of telegraphy. In 1860 he became connected with a number of gentlemen who proposed to form a joint-stock company to purchase and work his system of telegraphy, and it was agreed that he should become the electrician and chief engineer of the company at a salary of £2,000 per annum, and should receive £10,000 in cash and £15,000 in fully paid-up shares of the company, with a royalty for the use of his patents. Mr. Allan afterwards received notice that this agreement had been rescinded, and subsequently the company received £636,000 from the Government for their undertaking, whereupon Mr. Allan brought the present action to enforce the agreement. The Queen's Bench decided against his claim, and their decision was supported by the Court of Appeal. Mr. Allan having died, the present appeal was brought by his executor. Their lordships now affirmed the decision of the Court below, and dismissed the appeal.

Earthquake in the West of England.—On Monday last a shock of earthquake was felt in many parts of Cornwall, and particularly on the north coast, and occasioned considerable alarm throughout the county. At Bude the shock is described as being of an extraordinary character, and not only was it felt there but all along the coast. The shock was quick and sharp, but sufficient in force to shake the houses to their foundations, and to cause a sensible oscillation of furniture in the rooms. In several instances articles of glass and crockery were thrown down and broken. At Stoke Climsland two shocks were experienced, the first about half-past one and the second half an hour later. The rectory house, a large and substantial building, shook very perceptibly, and some members of the rector's family who were in the church at the time state that the church also was shaken, and that chains hanging from the roof, from which in winter coronas are suspended, oscillated for some minutes. Some scaffolding, erected round the church to enable painting operations to be carried on, also shook as if it would fall. At Launceston and neighbourhood there were two distinct shocks. There was a low rumbling noise heard as of a heavy waggon passing, accompanied by considerable vibration, and the windows of the houses and shops were shaken for several seconds. A second shock was not so severe as the first; but there was no mistaking it. Similar reports have been received from Horrabridge, Lawhitton, Calstock,

Digitized by Google

Southpetherwin, and other places in the county. Later accounts show that the earthquake in the West of England was more general than at first supposed. Not only was it felt in North Devon and Central Cornwall, but it appears to have extended above the South Devon and Cornwall coasts. As far west as St. Blaze a glass was shaken out of a rack and broken. At Plymouth the vibrations were so slight as not to attract general notice, but it is now evident that they were felt in the environs, but in the town were mistaken for the passage of heavy vehicles.

Professor Tyndall and the Board of Trade.—In reference to Professor Tyndall's resignation of his position as Scientific Adviser to the Board of Trade, Lord Sudely stated in the House of Lords, on the 21st inst., that it was not the fact that the Corporation of Trinity House or the Board of Trade had acted towards him in a high-handed manner. He resigned because he did not approve of the constitution of the Committee of Inquiry, and because he did not think that with Mr. Wigham and Sir James Douglas on it as patentees there would be a fair trial. He also made certain charges against the Board of Trade and Trinity House, saying that for many years past the board had not given proper support to the gas system, and that in 1879 the system was actually brought to the verge of destruction. A great deal of what occurred had taken place before the present Government came into office. Since then everything had been done that could be done in the matter. The Corporation of Trinity House, the Commissioners of Northern Lights, and the Board of Trade agreed that the charges made by Professor Tyndall were quite unfounded. He had stated his grounds for thinking that the gas light was decidedly the best, and said that the experiment had proved it; but the fact was that there had been no experiments whatever. The position of the Board of Trade in the matter was that of a mediator between the lighthouse authorities, who differed on the question—certainly as regarded gas and oil—the Commissioners of the Irish Lights having expressed themselves as being decidedly in favour of the former, whilst the Commissioners of Northern Lights and the Trinity Board had taken an opposite view. The Board of Trade were only desirous that the question should be fairly tested; and after Mr. Chamberlain had made inquiries personally in Ireland, and consulted the authorities on the subject, it was resolved that there should be a more extended inquiry than could be had by the original committee, and that a new committee should be appointed. The preliminary trials were, therefore, given up. Professor Tyndall expressed himself very strongly with respect to Mr. Wigham and Sir James Douglas as members of the committee, on the ground that, as he maintained, both were prejudiced—the one as to gas and the other as to oil. The former was a manufacturer, but the latter was not, and incurred all the expenses of his patent without any contribution from the Board of Trade. Soon after this, the President of the Board of Trade had an interview with Professor Tyndall, and, having gone into the question fully with him, came to the conclusion that it would be far better to have some other authority thoroughly impartial to assist the board as their scientific adviser besides Professor Tyndall, and to appoint Mr. Vernon Harcourt. Professor Tyndall was, undoubtedly, a gentleman who stood very high in the scientific world, and was well known for his independence and integrity, but it was also well known that he was a gentleman who was apt to take very strong views, and, having taken those views, he was the most difficult man in the world to get to alter them. He (Lord Sudeley) was sorry to have to say, but he felt bound in justice to the Board of Trade to say it, that in his correspondence with the board Professor Tyndall had shown throughout a disposition to impute motives to other people, and pecuniary interests to different gentlemen of the committee, which the Board of Trade thought he certainly ought not to have done.

Overhead Wires. — Deputation to the Local Government Board.—On Monday afternoon a deputation from the vestries of Marylebone, St. George's, Hanover-square, and St. James's, Westminster, accompanied by representatives from most of the other metropolitan vestries and boards, including the City Commissioners of Sewers, waited upon Sir C. Dilke, M.P., at the offices of the Local Government Board, with the object of seeing what steps could be taken to put a stop to the dangerous practice of fixing telephone and telegraph wires over the streets of the metropolis. After pointing out the danger which was created by the ever-increasing number of wires that were being placed over the streets, Sir Arthur Hobhouse said some persons seemed to think that the vestries could interfere in the matter and prevent the erection of them, and were even liable for damages should any accidents occur. The Government were, however, the proper authority to deal with a new practice of this nature, there being no adequate law, so far as he was aware, to enable the vestries to meet effectually the exigencies of the case.—Sir C. Dilke, in reply, said that the general view the Government took upon the matter was that the owners of the wires had no greater rights of interfering with the public streets and placing wires across them than any member of the public. They were in the position of any ordinary individual. The Government did not think that such persons could, either with or without the assent of the local authorities, interfere with public highways in such a way as to cause obstruction to the public, even though such obstruction was limited to the time during the execution of those works. The Government were not prepared to say that in all cases it would be unlawful to carry wires across the streets where the consent of the owners of the buildings had been obtained. It would be a question of fact in each case whether the wires so suspended were the source of such probable danger as to constitute a nuisance, and that would depend upon a number of considerations, such as the width of the streets, the number of the wires, and the distance they were apart. No doubt a great danger did exist owing to these overhead wires, and the question was whether in the face of so great a risk the vestries had not the power to interfere. He agreed if they had not such powers they ought to be obtained, and that it ought to be made quite clear whether they had such powers or not. It was mentioned by one of the speakers that there were miles of overhead wires in the metropolis for which no owners could be found, and that was a fact of importance, as the wires would be allowed to get out of repair through neglect, and accidents would ultimately follow. He thought it very probable, if the case were tried, that it would be found that the vestries had sufficient powers to prevent the erection of overhead wires; and it was desirable that they should be clear on that point before any legislation was attempted. If it were found that the local authorities had no power to control the erection of these wires, then he was of opinion that legislation on the subject should take place, the proper body to initiate which ought to be the Metropolitan Board of Works. He could not, however, but think that the present law would be found sufficient to deal with the question, and he would be sorry to initiate general legislation upon it unless it were made quite clear such was not the case. The deputation then withdrew.

CURRENT ENERGY.—V.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 105.)

Given a magnet placed near a closed circuit with no current in it. There is *no* mutual force when they are at rest, and it is not immediately evident that there should be any when the magnet or the conductor is moved. But, following Helmholtz, if we start with a current in the conductor, kept up by a constant E.M.F., we can go further. For now there is force between them, exactly determinate when the data of shape. &c., and strength of current and of magnetisation, are given. Let the positions be such that there is a repulsion of whole amount F, so that a pressure of this amount must be applied to prevent the magnet and conductor separating further. Now push the magnet towards the current through the space dx. The amount of work externally spent against the force F during the operation is Fdx, and by the principle of the conservation of energy an equal amount of energy is put into the system, and must be accounted for somewhere. But where to look for it conservation will not tell us, and more facts are needed to assist us to a definite conclusion. As a matter of fact, the work spent is accounted for finally as heat in the conductor. How it gets there is a mystery. The current in the conductor is increased by the motion of the magnet, the rate of transfer of energy from the battery is also increased, the generation of heat which is inseparable from the existence of conduction currents is likewise increased, and this additional generation of heat is the equivalent of the additional energy leaving the battery *and* of the external work spent against the electro-magnetic forces. This is sufficiently complex, but the reality is even more so, for the above supposes that the motion is such that the induced current is not changing, that is, that the actual increased current remains steady. We see, however, preliminarily, that the energy put into the system externally by moving the magnet must exist in at least one intermediate form before it becomes heat in the wire, for it has to be transmitted across the intermediate space and the heat is not generated at the place of external work, as when a button is rubbed upon the coat sleeve. Now, this intermediate energy must also be taken into account when the induced current is not steady, for then there will be no longer equivalence between the rate of generation of heat and the rate of supplying energy from the battery and from the external source, the difference going to the intermediate form.

But to develop this matter it becomes necessary to take a general view of the connection of Ohm's law with Joule's law, and the principle of conservation as concerned in the transfer of energy from a battery in *steady* action. As regards Ohm's law, if there is little to be said that has not been said over and over again, it is certain that a good deal of nonsense has been written about it. Perhaps no scientific law has had so much unscientific discussion, a result to be attributed in the main to its remarkable practical importance bringing it down from the professors to the multitude, which must always contain amongst the great mass who are willing to learn, and are too modest to imagine, if they cannot understand a thing, that the professors are all wrong, a certain number of self-confident paradoxers, whose peculiar conceit is that their views are necessarily right. Self-confidence is, no doubt, an excellent thing in its way, but when coupled with ignorance of the fundamental truths of dynamics (which they should know is an *exact* science), leads to extraordinary jumbles sometimes. Did they only deceive themselves in their delusions little harm would be done, but when they take to writing books for students, then, Lord save us! a whole body of blind followers is precipitated into the ditch of mental confusion, from which extrication is so difficult, and whose mud sticks for so long.

In any conductive metallic circuit in which a steady current is flowing, if there be any connection at all between the current C and the whole electromotive force E in the circuit, we may write $E = f(C)$, some function of the current, and, it may be, of other quantities. Or we may say $E = RC$, where R is the ratio of the E.M.F. to the current, and R may be a function of the current and of other quantities. Now, according to Ohm's law, this ratio is constant for a particular circuit, that is, is independent of the current. Increase the E.M.F. in any proportion, and the current will be increased in the same proportion. There is a reservation to be made, viz., that the temperature must be kept constant, otherwise the ratio will slightly change. Also another of lesser immediate importance that the long-continued passage of currents may slightly alter the ratio, a result probably due to some structural alteration produced in the conductor. And minute changes may be due to other causes, but practically the ratio is a constant.

What is true for a complete circuit is also true for any portion thereof, the ratio of the E.M.F. in that portion to the current is constant, and this naturally leads us to the most general way of stating Ohm's law, which is to take the unit volume (cube) of a conductor, with two opposite faces perpendicular to the current, and apply the law to it. Let e be the E.M.F. between the faces mentioned, and c the current crossing them and every intermediate section of the cube, then $e = rc$, where r is constant for the *material*. Here e is the E.M.F. per unit of length (or E.M.F. at a point) c the current per unit area (the current density, or current at a point), and r the specific resistance per unit volume.

Another useful form is $c = ke$, where k, the constant ratio of the current to the E.M.F., is the specific conductivity, the reciprocal of r.

Corresponding to $c = ke$ in a conductor we have $D = Ke$ in a dielectric, where D is the displacement produced by the E.M.F. e, D referring to unit surface and e to unit length as before, and K being a constant for the material.

Again, we have in induced magnetisation the analogous law $B = \mu H$, where μ is the ratio of the magnetic induction B to the magnetic force H. And similarly $I = \kappa H$, where I is the magnetisation produced by H, and κ their ratio.

But the constancy of K in any dielectric is by no means well assured, whilst in solid dielectrics there is the complication introduced by the phenomenon of "absorption," making the value of K appear to vary according to the time the E.M.F. has been acting upon the dielectric, and the displacement already produced, a phenomenon analogous to the effects of imperfect elasticity in bodies under stress.

And κ and μ in magnetisation are only constants (approximately) for weak magnetic forces; their values fall very rapidly when the force is greatly increased, a limiting maximum magnetisation being reached.

On the other hand, Ohm's law is remarkable in that the ratio r remains constant from the lowest to the highest E.M.F.'s, a constancy which could not be predicted or expected *à priori* with any certainty in our ignorance of the nature of what is really going on in a body carrying a current.

The constancy of r implies that the existence of one current in a wire does not in any way alter the wire so as to interfere with its capacity for bearing another current if the required additional E.M.F. act, which is very different from the superposition of magnetisations, where the effect of additional magnetic force depends upon the already existing state of magnetisation. An immediate consequence is that any number of E.M.F.'s may be superimposed at any point of a conductor, the resulting current being the algebraical sum of the currents the E.M.F.'s would separately produce if they act all in the same line; and when their directions are not all the same, the resultant current and resultant E.M.F. have the same direction, and have the same ratio of magnitude r as any of the component E.M.F.'s and currents, of which they are the vector sums.

With the application of Ohm's law to practical circuits and its developments we have no concern here, but a few remarks as to some misunderstandings may not be out of place.

The constant R in $E = RC$ is called the resistance of the circuit (or portion thereof, as the case may be). Notice that it is "called" so. Now, students are sometimes led, or rather misled, by the name and by certain ideas they may possess as to frictional resistance to imbibe the idea that R is really analogous to the frictional resistance to the flow of water through a pipe, when the current of water is compared to the electric current. To credit them with supposing it to be not merely analogous to, but actually frictional resistance,

Digitized by Google

would be to place them in the category of "men of science who are not natural philosophers," described by Maxwell, who seized on the word Fluid as something intelligible, and forthwith endowed electricity along with fluidity, with mass, inertia, &c. But still the student, if he avoids the error of the knowing men who loved not Sophia, may be temporarily under the delusion that R is analogous to frictional resistance. That it is not so he soon finds out, as a general rule, when he gets a little further into the matter. Should he, however, be unfortunate enough to keep the idea long enough to allow it to crystallise, it requires later a great effort to get rid of it. Then, when the time comes, he, after profound cogitation, rises up and repudiates the idea, and perhaps rushes into print with his discovery, reminding one of the example of the atheist (who was a thief) who made the bold declaration that so startled his hearers, that "todestools *ain't* what the todes sit down on, but is just *called* so." Exactly, R is just called so.

The real analogue to the frictional resistance of water flowing through a pipe is not R, but RC in the electrical case. Thus, if we set water in a pipe in motion, driving it by means of a constant difference of pressure between its ends, the velocity will increase until the motive force is just balanced by the frictional resistance. Now, let the frictional resistance be exactly proportional to the velocity, as it is said to be approximately for low velocities in thin pipes. Then, if C' be the current, $R'C'$, where R' is some constant multiplier, will be the frictional resistance, and C' will increase until $R'C'=E'$, which gives the steady current corresponding to the motive force E', after which there will be no further acceleration of velocity.

Now, representing the difference of pressure by the E.M.F. in the wire, and the current of water by the electric current, the analogue of frictional resistance in the pipe is RC, and the constancy of R (which is analogous to the coefficient of friction) implies that the resistance is proportional to the current.

Again, if ideas are correct, it is of secondary importance what language is used to express them, but it certainly would appear that, when people say that a certain E.M.F. is required to enable the current to *overcome* the resistance of a wire, it is the idea that is wrong. For there is really no question of overcoming, though there is of coming over. To every E.M.F. corresponds its definite current, neither more nor less. To give a parallel case in mechanics. A body resting on a level surface is set sliding under the application of a constant force; what velocity it will assume depends upon the friction when in motion, since there is no lifting work done. Assuming, for the sake of argument, that it is proportional to the velocity v, say Rv, where R is the coefficient of friction, and that F is the applied force, $Rv = F$ determines the steady velocity similarly to the case above. The final velocity and the applied force are in a constant ratio. Here there is no question of overcoming, for it is the motion that brings the resistance.

But if the body be at rest, there will be a definite force required to set it moving at all, depending upon the statical friction. There is really a resistance to be overcome before the body will move. But this has no analogue in conduction currents in metals; the least E.M.F. will set up its corresponding current, down to the smallest measurable, and there is no initial resistance to be overcome. In gases, however, there appears to be something of the kind, and naturally we find it expressible as E and not as R. Thus Mr. Varley found that 323 cells were required to start the current in a certain tube, although when set up the current was that due to the excess of the E.M.F. over 304 cells, following Ohm's law thereafter. The initial $E = 323$ Daniells is analogous to the statical friction. For the rest, the analogy is not a good one for our purpose.

Ohm's classical memoir of 1827, "The Galvanised Kettle Mathematically Tinkered," of which a translation is to be found in Taylor's "Scientific Memoirs," contains a good deal more than $E = RC$. Therein will be found the laws of distribution of potential in different parts of a circuit, with the well-known zig-zag lines showing its changes in passing through a battery of many cells. Also, if I remember rightly, the method of joining up cells to get the maximum current in a given external resistance, and the corresponding law for the size of wire of a galvanometer. There is, besides, an analytical investigation relating to the propagation of electricity in a wire, wherein, proceeding upon an entirely erroneous assumption regarding the power of a wire for storing up electricity in its bulk, like heat, following in fact Fourier's investigation of the conduction of heat, he was led to the true equations for the propagation of potential in a long wire, with electro-magnetic induction neglected, afterwards legitimately established by Sir W. Thomson, and he gave the solution in the case of a constant E.M.F. put on at the beginning of a wire, the end being to earth. Why he should have come to the right result by a wrong method was simply that, whether electricity is stored up in the substance of a wire, or goes to the surface and stays there, the equations are of exactly the same form.

(TO BE CONTINUED.)

ON THE RESISTANCE OF THE ELECTRIC ARC.

By O. FRÖLICH, from the *Electrotechnische Zeitschrift*, April, 1883.

Opinions as to the nature of the resistance in an electric arc are very various, even at the present day. Perhaps the first work upon the subject is that by Edlund (*vide Poggendorf's Annalen*, v. 131, p. 586). In this the arc is compared to a galvanic cell, and preserving the analogy, the induced counter E.M.F. and the true resistance of the arc are determined experimentally in a number of cases.

Edlund's work has not been in requisition of late, probably because he worked only with batteries and very moderate lights, and hence his results are not directly applicable to the intense lights of the present time. On the other hand, there is the question whether or not the arc possesses a counter E.M.F., and attempts have been made to settle it experimentally. This is difficult, and it is indeed doubtful whether it is even possible to arrive at an experimental proof. Among the many attempts of this kind I know of none by which the existence of a counter E.M.F. is proved with anything like certainty.

In many scientific and technical works we meet with the rule that the E.M.F. of the arc, measured between the two carbons, has a fairly constant value, about 50 volts (see, for instance, Richter, *E. Z.*, 1883, p. 29). I am convinced that many constructors apply this rule, though, as far as my knowledge extends, it has not been submitted to a more exact examination.

That the rule cannot be strictly true is proved by the consideration that according to it the electrical elements of the arc would have to be independent of the length. This is contrary to the fact that the resistance of the arc, when the current is maintained constant, increases with the length of arc. This fact lies at the root of all constructions of electric lamps, and is unquestionable.

The resistance of the arc is the relation between the E.M.F. between the carbons and the current. We will call it the apparent resistance, because we are as yet uncertain that an induced counter E.M.F. is not produced, and the resistance in this case will not be an element of the same physical character as in the case of an ordinary conductor.

The apparent resistance of the arc depends upon the current and the length of arc. For the nature of this dependence we require observations in which these quantities have the most different values possible, and these the trials of Messrs. Siemens and Halske, given in Table I., afford us, from which we will endeavour to educe the function desired.

To detect directly the law for the apparent resistance is hard, because it depends upon two independent variables. It is better to see if in the connection between the E.M.F. and one of the variables the other does not disappear, or, perhaps, appears only to exert an unimportant influence.

Let the observations be so plotted that abscissæ represent lengths of arc and ordinates E.M.F. Then we arrive at the figure (see page 152), which is a zig-zag line. The cause of the irregularities of this line is to be looked for chiefly in the fact of the observations having been taken at different times by different observers, and with different instruments, but partly in the E.M.F. not being merely a function of the arc-length, but depending in part on the current, as does the apparent resistance.

Even if such be the case, at all events the observations show that with a constant length of arc the E.M.F. is greater with a small current than with a large one. This corresponds with the case of a galvanic cell, but I do not wish to consider this point as proved before it has been made the subject of more exact experiments. We can only conclude with certainty from the above curve that the E.M.F. increases with the length of arc, and, indeed, that the ratio of increase is fairly uniform, being represented by the straight line T T.

Thus, if E is the E.M.F., L the length of arc, and *a* and *b* co-efficients, we have

(1) . . . . $E = a + b\,L$,

or, numerically, when E is measured in volts and L in millimeters,

$$E = 39 + 1{\cdot}8\,L.$$

Digitized by Google

The apparent resistance R of the arc is obtained directly from the E.M.F. and the current C, thus :—

$$(2) \quad . \quad . \quad . \quad . \quad R = \frac{E}{C} = \frac{a}{c} + b\,\frac{L}{C},$$

or, numerically,

$$R = \frac{39}{C} + 1{\cdot}8\,\frac{L}{C}.$$

To show the agreement of these formulæ with the results of the trials of Siemens and Halske, the calculated values of E.M.F. and resistance have been registered in the table already given.

By means of these formulæ Table II. has been calculated, which will be found to be sufficiently accurate for practical technical purposes.

The question now arises whether from these formulæ anything can be gathered as to the preference to be given to one of the two views of the nature of the arc, the polarisation view, and the passage-resistance view. Taking first the polarisation view,

Let E' be the polarisation, or counter E.M.F.
k the co-efficient of specific conduction.
Q the cross section of the arc.
E the E.M.F. between the carbons.
R the apparent resistance.

For the meanings attaching to the symbols a and b we see that when $c = 1$, or when the unit of cross section is taken to be that traversed by a unit of current, a is the value of the counter E.M.F. on the one hypothesis, and the resistance between the arc and carbons for a unit cross section of arc on the other; b is, on either supposition, the reciprocal of the co-efficient of specific conduction in the arc.

We see, moreover, that the results of experiment are in keeping with either hypothesis, or, indeed, with a combination of the two.

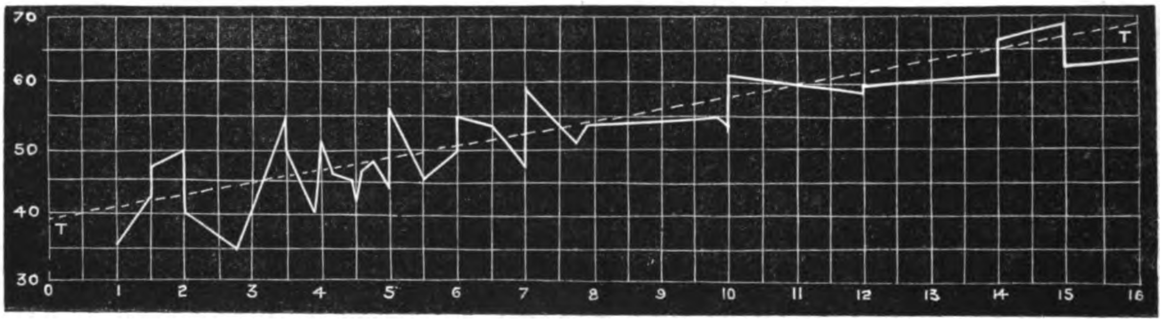
For the polarisation view we have the difference in the appearances of the carbons, and the fact that a minimum E.M.F. is required to form an arc at all.

Against this view, and for the passage-resistance view, may be urged the high value of the counter E.M.F., which is some ten times greater than all known cases of polarisation.

For the value P of the power consumed in the arc, we have $P = E\,C = (a + b\,L)\,C$. . . . . (3)

It is therefore proportional to the current, and is converted into radiant heat and light for the most part; but it is partly employed in the mechanical breaking up of the carbon particles. In these operations the power derived from the combustion assists, which also generates light and heat.

When we think that what is called the intensity or strength of the light of an arc only means the light radiation in a



Then

$$\left.\begin{aligned} E &= E' + \frac{1}{k}\cdot\frac{L}{Q}\,C \\ R &= \frac{E'}{C} + \frac{1}{k}\,\frac{L}{Q} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (a)$$

Next suppose there is no polarisation, but at the passages between the arc and the carbons a resistance whose specific value is $r_{,}$, and whose total value, therefore, is $\frac{r_{,}}{Q}$. Then,

$$\left.\begin{aligned} E &= \frac{r_{,}}{Q}\,C + \frac{1}{k}\,\frac{L}{Q}\,C. \\ R &= \frac{r_{,}}{Q} + \frac{1}{k}\,\frac{L}{Q} \end{aligned}\right\} \quad . \quad . \quad . \quad . \quad (b)$$

Now, if we compare the formulæ a and b with the former formulæ obtained by experiments, 1 and 2, we see that a and b are both brought into congruity with 1 and 2 by the same supposition, viz., that the section of the arc Q is proportional to the current C. When we make this supposition—and it is known that the cross section does increase with the current—and write $Q = c\,C$, we get

$$\text{from } a \quad . \quad . \quad . \quad \left\{\begin{aligned} E &= E' + \frac{1}{k\,c}\,L \\ R &= \frac{E'}{C} + \frac{1}{k\,c}\,\frac{L}{C}. \end{aligned}\right.$$

$$\text{from } b \quad . \quad . \quad . \quad \left\{\begin{aligned} E &= \frac{r_{,}}{c} + \frac{1}{k\,c}\,L \\ R &= \frac{r_{,}}{c\,C} + \frac{1}{k\,c}\,\frac{L}{C} \end{aligned}\right.$$

all in congruity with formulæ 1 and 2,

horizontal direction, it is clear that this intensity is only a very imperfect expression of the power resident in the electric current. However this may be, the view so generally maintained of late, that the intensity of the light is proportional to the current, receives only support from the formula (3).

THE FIRST TELEPHONE.*

BY PROFESSOR SILVANUS P. THOMPSON.

On the 12th of May, 1862, there was met together in a fine old hall in the City of Frankfort-on-the-Main a crowded audience, eager to see and hear the latest scientific invention expounded by its inventor. The occasion was the meeting of the Free German Institute (Freies Deutsches Hochstift), a sort of literary and philosophical society, which has since domiciled itself in the historical old house where Goethe was born. The invention which attracted so notable a crowd was the telephone. The inventor was Philipp Reis, a teacher of natural sciences in Garnier's Institute, a flourishing boys' school at Friedrichsdorf, near Homburg.

On one occasion previously had the telephone been publicly exhibited; namely, at a meeting of the Physical Society of Frankfort, on the 22nd of October in the preceding year.

In the *Journal* of the Frankfort Society (Jahresbericht des Physikalischen Vereins zu Frankfurt am Main) for 1860-61, p. 57, may be found the memoir of Philipp Reis on the subject, under the title "On Telephony by the Galvanic Current." In this memoir, which shows a marvellous precision and a grasp of the subject that excites admiration and wonder, the author says :—"I have now succeeded in constructing an apparatus by means of which I am in a position to reproduce the tones of divers instruments, and even to a certain degree the human voice." The inventor

* [Reprinted from the *Proceedings of the Bristol Naturalists' Society.*]

Digitized by Google

further says:—"Since the length of the conducting wire may be extended for this purpose just as far as in direct telegraphy, I give to my instrument the name 'Telephone.'" Toward the end of the memoir it is stated that until now it had not been possible to reproduce the tones of human speech with a distinctness sufficient to satisfy everybody; adding:—"The consonants are for the most part tolerably distinctly reproduced, but the vowels not yet to an equal degree." The author of the memoir in which these statements occur had been led to his invention by a remarkably suggestive line of thought. He had wanted an instrument

FIG. 1.

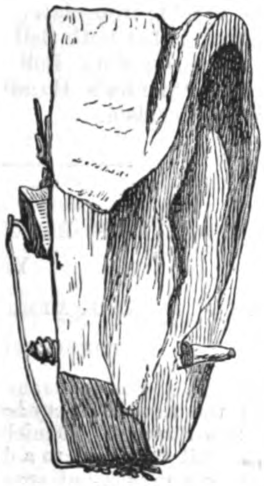


FIG. 2.

to transmit electrically everything and anything that a human ear could hear. Accordingly he took the human ear itself as a model. "How," he argues, "could a single instrument reproduce at once the total actions of all the organs operated in human speech? This was ever the cardinal question. At last I came by accident to put this question another way:—How does *our ear* perceive the total (or resultant) vibrations of all the simultaneously-operant organs of speech?" He then goes on to describe the action of the auditory ossicles when the ear is made the recipient of sound; pointing out how they execute movements and exert forces

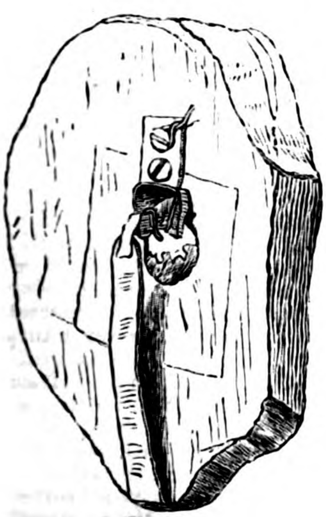

FIG. 3.

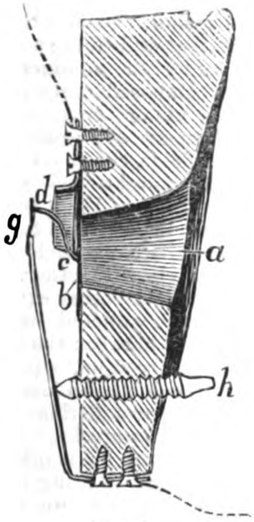

FIG. 4.

upon one another in proportion to the condensations occurring in the sound-conducting medium and to the amplitudes of vibration of the tympanum. Having stated this law of proportion between the cause and its effect, he goes on to speak of the graphic method of representing varying forces, such as those of sound-waves, by curves, and emphatically lays down that the ear is absolutely incapable of perceiving anything more than can be expressed by such a curve. After giving samples of undulatory curves corresponding to musical and to discordant sounds, he makes the following significant remark:—"So soon, therefore, as it is possible at any place and in any manner to set up vibrations whose curves are like those of any given tone or combination of tones, we shall then receive the same impression which the tone or combination of tones would have produced upon us. Taking my stand upon the preceding principles, I have succeeded in constructing an apparatus," &c. He concludes his paper by saying that the newly-invented phonautograph of Duhamel may, perhaps, afford evidence as to the correctness of the views which he has asserted respecting the correspondence between sounds and their curves.

The actual apparatus figured in this memoir, and exhibited to the Frankfort Society in October, 1861, is now in my possession; and I have also temporarily entrusted to me a still earlier experimental telephone, made by Philipp Reis, in the form of a model of the human ear.* This interesting instrument is depicted in its actual condition and size in Figs. 1, 2, and 3, and in section in Fig. 4.

It is carved in oak-wood. Of the tympanic membrane only small fragments now exist. Against the centre of the tympanum rested the lower end of a little curved lever of platinum wire, which represented the "hammer" bone of the human ear. This curved lever was attached to the membrane by a minute drop of sealing-wax, so that it moved in correspondence with every movement of the tympanum. It was pivoted near its centre by being soldered to a short cross-wire serving as an axis. The upper end of the curved lever rested in loose contact against the upper end of a vertical

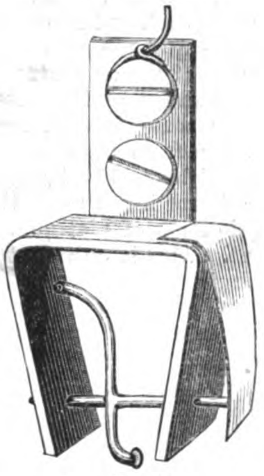

FIG. 5.

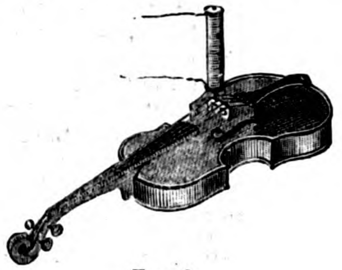

FIG. 6.

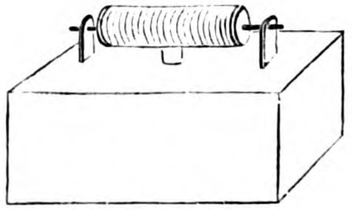

FIG. 7.

spring, about 1in. long, bearing at its summit a slender and resilient strip of platinum foil (see Fig. 4). An adjusting screw served to regulate the degree of contact between the vertical spring and the curved lever. Conducting wires, by means of which the current of electricity entered and left the apparatus, were affixed to screws in connection respectively with the support of the pivoted lever and with the vertical spring. A springy strip of platinum pressed against the end of the pivot of the lever (as shown enlarged in Fig. 5) to ensure good electrical contact.

If now any words, or sounds of any kind, were uttered in front of the "ear," the membrane was thereby set into vibrations, as in the human ear. The little curved lever took up these motions precisely as does the "hammer" bone of the human ear; and, like the "hammer" bone, transferred them to that with which it was in contact. The result was that the contact between the upper end of the lever and the spring was caused to vary. With every rarefaction of the air the membrane moved forward, and the upper end of the little lever moved backward, and pressed more firmly than before against the spring, making better contact, and allowing a stronger current to flow. At every condensation of the air the membrane moved backwards and the upper end of the lever moved forward, so as to press less strongly than before against the spring, thereby making

* The property of Léon Garnier, Esq., Director of Garnier's Institute at Friedrichsdorf, near Homburg, where Philipp Reis was formerly teacher of natural sciences.

Digitized by Google

a less complete contact than before; and, by thus partially interrupting the passage of the current, caused the current to flow less freely. The sound-waves which entered the air would in this fashion throw the electric current, which flowed through the point of variable contact, into undulations in strength. Reis himself termed the contact-part of his telephone an "interruptor." That it was not intended to operate as an abrupt make-and-break arrangement, as some persons have erroneously fancied, is evident; firstly, because the inventor introduced delicate springs to give a following-contact (like that in Blake's well-known "transmitter"), and so prevent abrupt breaks from occurring; secondly, because abrupt breaks would have violated the fundamental principle to which he refers in the sentence immediately preceding his description of the instrument shown to the Frankfort Society, namely, that of creating tones whose curves were like the undulatory curves imparted at the transmitting end of the instrument; thirdly, because (in another article) he described his instruments as opening and closing the circuit in proportion to the sound-wave; which obviously an abrupt "break-and-make" apparatus without a spring-contact could not possibly do. The mechanism which Reis thus invented—and which is substantially alike in all his instruments—might be appropriately described as the combination of a tympanum with an electric current-regulator; the essential principle of the electric current-regulator being the employment of a loose or imperfect contact between the two parts of the conducting system; those parts being so arranged that the vibrations of the tympanum would alter the degree of contact, or occasion an approach and recession of the atoms of the two surfaces, and so vary the resistance offered at the point of contact to the flow of the current.

The particular form of the instrument shown at Frankfort in 1861, and described in the *Journal*, is somewhat different from the "ear." The description is taken from the *Journal*.

"In a cube of wood there is a conical hole, closed at one side by the membrane (made of the lesser intestine of the pig), upon the middle of which a little strip of platinum is cemented as a conductor of the current. This is united with the binding-screw *p*. From the binding-screw *n* there passes likewise a thin strip of metal over the middle of the membrane, and terminates here in a little platinum wire which stands at right angles to the length and breadth of the strip. From the binding screw *p* a conducting wire leads through the battery to a distant station." In the original instrument there is also an adjusting screw to regulate the contact, though this was not shown in the drawing in the *Frankfort Journal*.

The receiver used to reproduce the sounds transmitted by these telephones is also described in the memoir of Reis. It consisted of a steel needle surrounded by a coil of wire. This was at first set up—for the purpose of increasing the sounds by resonance—upon the top of a violin, as shown in Fig. 6; later it was mounted upon a pine-wood box, as in Fig. 7; to which still later a lid of thin pine was added, against which the listener could press his ear. The sounds emitted by such a wire during magnetisation and demagnetisation were well known before, but to Reis is due the discovery that other tones than the natural vibration-tone of the wire could be electrically imposed upon it by the varying magnetising power of the current traversing the surrounding coil. Reis explained the reproduction of the transmitted sounds by supposing a magnetic attraction between the atoms of the steel wire to work synchronously with the fluctuations of the current. He later devised a different receiver, in which an electro-magnet was provided with an elastically-mounted armature of iron attached to a light and broad lever, which it threw into vibrations corresponding to those of the original sound waves. With this apparatus, and a transmitter with a small curved-lever, in shape like that in the "ear," he was able (see Kuhn's "Handbuch der Angewandten Elektricitätslehre," 1866, p. 1,021), not only to reproduce melodies with astonishing exactness, and single words as in speaking and reading less distinctly, but even to transmit the inflexions of the voice expressive of surprise, command, interrogation, &c.

Considering how far these early researches were carried, it is remarkable that their historic value has been so greatly overlooked. The transmitters which Reis devised embody—though their mechanical design is less perfect and their performance consequently less certain—all the essential principles of the telephonic transmitters in use to-day, such as Blake's, Berliner's, and Crossley's. The receivers devised by Reis, more particularly the second form, anticipate every principle essential in the more modern and convenient receiver of Graham Bell, having an electro-magnet combined with an armature capable of inductive action, *i.e.*, made of iron, elastically mounted, and having an extended surface. Bell made the very great improvement of uniting these three qualities, essential to the armature, in one, by employing as armature a thin flexible iron plate. It is but just to the later inventors to add that both Bell and Edison have explicitly referred to Reis's prior work, Bell even going so far as to name the pages of "Kuhn's Handbook" from which the preceding reference is taken.

A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

(CONTINUED FROM PAGE 120.)

Experiments on the transmission and velocity of electricity, to which the new discovery lent a fresh and fascinating interest, were now resumed. Daniel Gralath, early in 1746, was the first to transmit the shock to a distance, which he did by discharging a battery, composed of several jars, through a chain of twenty persons, with outstretched arms. In May, 1746, Joseph Franz, at Vienna, discharged a jar through 1,500ft. of iron, and in the following July, Winkler charged, as well as discharged, a battery of three jars through an insulated wire thirty ells long, and laid along the bank of the river Pleisse, whose waters formed the return half of the circuit.†

The Abbé Nollet, whose name is famous in the annals of this period, had meanwhile taken up the subject in France. He first, April, 1746, transmitted the shock of a Leyden jar through a chain of 180 of the Royal Guards at Paris, and soon after performed a grander experiment of the same kind at the Carthusian convent. By means of iron wires stretched between every two of the monks he formed a large circle of 5,400 feet through which he discharged his jars, with the result in every case that at the moment of discharge all the persons in the circuit gave a sudden spring, showing that the shock was felt by each at the same instant and to the same degree of intensity.

Lemonnier, the younger, also of Paris, employed still longer circuits composed of two thousand toises (12,780 feet) of iron wire laid along the ground, and, although some of the wire dragged upon wet grass, through hedges, and over newly-ploughed fields, the shock was in no way diminished, a fact which was then thought very surprising. In other experiments he made use of two large basins of water in the gardens of the Tuileries. In April, 1746, in the court of the Carthusians he so laid out two parallel wires of 5,700 feet each that all four ends were close together. Between one pair he placed a jar, and grasped the other extremities himself; then on causing the circuit to be completed, he could not distinguish any interval (so short was it) between the spark at the jar, and the shock through his arms ("Priestley," pp. 92—5).

Upon receiving an account of these performances from Lemonnier, our own distinguished countryman, Watson, took up the inquiry, and pursued it so successfully as not only to eclipse the achievements of his neighbours, but to gain for himself in after years the credit of being the first to propose an electric telegraph—an idea which, as we will presently see, is quite erroneous.‡ Watson's experiments were very numerous, and were carried out on a grand scale, under the auspices of a committee of the Royal Society, consisting of Mr. Folkes, Lord C. Cavendish, Dr. Bevis.

* The author reserves all rights of translation.

† Winkler had previously, in 1744, ascertained that the rapidity of an electric discharge was exceedingly great and comparable with the speed of lightning. He also, as the result of his experiments, concluded "that electricity could be transmitted to the ends of the earth, if a conducting body covered or insulated with silk be laid so far, it being only necessary to consider that there may be a certain amount of resistance to the transmission." "Thoughts on the Properties, Operations, and Causes of Electricity," Leipsic, 1744, pp. 146, 149.

‡ The suggestion has been claimed for Franklin and Cavendish, and with as little reason. It is time that writers on the telegraph ceased to bandy pretensions for which there is no foundation whatever.

and others. As preparing the way surely, though unsuspectedly, for the first suggestions of an electric telegraph these investigations must ever possess a peculiar interest for telegraphists, and we therefore make no apology for presenting to our readers the following detailed account of them, for which we are indebted to Dr. Priestley's work, pp. 95—102.

Dr. Watson, who wrote a full account* of the labours of the Committee for the Royal Society, begins with observing (what was verified in all their experiments) that the electric shock is not, strictly speaking, conducted in the shortest manner possible, unless the bodies through which it passes conduct equally well. The circuit, he says, is always formed through the best conductors, though the length be ever so great—a most sagacious observation for the man and the time—

The first trials took place on the 14th and 18th July, 1747, on a wire carried from one side of the Thames to the other over old Westminster Bridge. One end of this wire communicated with the interior of a charged Leyden jar, the other was held by a person on the opposite bank of the river, who also held in his other hand an iron rod which he dipped into the water. Near the jar stood another person holding in one hand a wire communicating with the exterior coating of the jar, and in the other an iron rod. On dipping this into the water and thus completing the circuit for the discharge, the shock was instantly felt by both persons, but more strongly by him who stood near to the jar—because, as Watson rightly stated, part of the electricity went from the wire down the moist stone work of the bridge, thereby making several shorter circuits to the jar, but still all passing through the observer who stood near it.

The next attempt was to force the shock through a circuit of two miles at the New River near London. This was accomplished on the 24th July at two places, at one of which the distance by land was 800 feet and by water 2,000; and at the other, 2,800 feet of land and 8,000 feet of water.

The disposition of the apparatus was similar to that at Westminster Bridge, and the results were equally satisfactory. On repeating the experiments, however, the rods, instead of being dipped into the water, were merely thrust into the ground about 20 feet from the water's edge. The result was the same, as it was found that the shock was equally well transmitted. This occasioned a doubt whether in the former case the shock might not have been conveyed through the ground between the two rods, instead of passing through all the windings of the river, and subsequent experiments showed that such was the case. Other experiments followed at the same place, on the 28th July, when for the first time the wire was supported in its whole length by dry sticks, and on the 5th August, at Highbury Barn when it was found that dry ground conducted the electric virtue quite as well as water.

Finally, on the 14th August at Shooter's Hill, an experiment was made "to try whether the electric shock was perceptible at twice the distance to which it had yet been carried, in ground perfectly dry, and where no water was near; and also to distinguish if possible its velocity as compared with that of sound." The circuit consisted of two miles of wire, and two miles of perfectly dry ground, but one shower of rain having fallen in the previous five weeks. The wire from the inner coating of the jar was 6,732 feet long and was supported all the way upon baked sticks, and that which communicated with the outer coating was similarly insulated, and was 3,868 feet long. The observers placed at the ends of these wires, two miles apart, were provided with stop watches with which to note the moment that they felt the shock. The result of a series of careful observations was that "as far as could be distinguished the time in which the electric matter performed its circuit might have been instantaneous."

Not satisfied, apparently, with this result, the inquiry was resumed in the following year, when a series of trials was performed after the manner of Lemonnier's Carthusian experiment of 1746. On the 5th August, 1748, a circuit of two miles was formed at Shooter's Hill by several turnings of wire in the same field. The middle of this wire was led into the same room as the Leyden jar, and there Watson placed himself in the centre of the line, taking in each hand the ends of the wire, and noting the spark with his eye while he felt the shock in his arms. Under these circumstances the jar was discharged several times, but in no instance could the observer distinguish the slightest interval between the moments at which the spark was seen and the shock felt; whereupon it was decided that the time occupied by the passage of electricity along 6,138 feet of wire was altogether inappreciable.

In 1748 Benjamin Franklin performed his celebrated experiments across the Schuylkill at Philadelphia, and De Luc some months later (1749) across the Lake of Geneva. Franklin thus playfully refers to his experiments at the end of a letter to his friend and correspondent, Peter Collinson, of London, dated Philadelphia, 1748:—

"Chagrined a little that we have hitherto been able to produce nothing in this way of use to mankind, and the hot weather coming on, when electrical experiments are not so agreeable, 'tis proposed to put an end to them for this season, somewhat humorously, in a party of pleasure on the banks of the Skuylkil. Spirits at the same time are to be fired by a spark sent from side to side through the river, *without any other conductor than the water*—an experiment which we some time since performed, to the amazement of many. A turkey is to be killed for our dinner by the electrical shock, and roasted by the electrical jack, before a fire kindled by the electrified bottle, when the healths of all the famous electricians in England, Holland, France, and Germany are to be drank in electrified bumpers, under the discharge of guns from the electrical battery."*

As the words that we have italicised in this extract are apt to mislead, and indeed have misled, some writers into supposing that Franklin here describes an experiment akin to that of telegraphing without wires, from which so much was expected forty years ago, we quote the following details from Vol. 1, page 202, of Franklin's works, London, 1806:—"Two iron rods, about 3ft. long, were planted just within the margin of the river, on the opposite sides. A thick piece of wire, with a small round knob at its end, was fixed on the top of one of the rods, bending downwards, so as to deliver commodiously the spark upon the surface of the spirit. A small wire, fastened by one end to the handle of the spoon containing the spirit, was carried across the river, and supported in the air by the rope commonly used to hold by, in drawing ferry boats over. The other end of this wire was tied round the coating of the bottle, which, being charged, the spark was delivered from the hook to the top of the rod standing in the water on that side. At the same instant the rod on the other side delivered a spark to the spoon and fired the spirit, the electric fire returning to the coating of the bottle, through the handle of the spoon, and the supported wire connected with them." The experiment was, therefore, precisely the same as that of Watson across the Thames, the only difference being in the words used to describe it. In the one case the discharge is said to go out by the water and return by the wire, and in the other to go out by the wire and return by the water.

Notwithstanding the singular suggestiveness of all these experiments, no one up to this time appears to have entertained the faintest suspicion of their applicability to telegraphic purposes; or, indeed, to any useful purpose whatever. Thus Watson, in a letter to the Royal Society, says:—"If it should be asked to what useful purposes the effects of electricity can be applied, it may be answered that we are not yet so far advanced in these discoveries as to render them conducive to the service of mankind," but, he adds, "future philosophers may deduce from them uses extremely beneficial to society in general." This was in 1746, and with reference to his then recent ignition of spirits by the spark; but even after his brilliant experiments in the following years, of which we have just given an account, he does not appear to have formed any more hopeful view. We also find the great Franklin, who was always in search of the practical in science, positively expressing his disappointment in the letter just quoted at being unable to find any useful application of electricity.†

* "An account of the experiments made by some gentlemen of the Royal Society," &c., 8vo., London, 1748.

* "An electric battery, famous because it was once owned and operated by Benjamin Franklin, and other distinguished scientific men, has been in constant use at Dartmouth College for years, and is now employed almost daily for class-room experiments in physics. It was at one time in the hands of the celebrated Dr. Priestley, the discoverer of hydrogen."—(American newspaper.) Another interesting relic—Faraday's first electrical machine—is still in vigorous action at the Royal Institution, and was used by Dr. Gladstone to illustrate his Christmas Lectures in 1874-5.

† His suggestion of the lightning-conductor was not made until towards the end of July, 1750, for which he was indebted to an experiment of his friend, Thomas Hopkinson. This philosopher electrified a small iron ball, to which he fixed a needle, in the hope that from the point, as from a focus, he would draw a stronger spark. Greatly surprised at finding that, instead of increasing the spark, the point dissipated it altogether, he mentioned his failure to Franklin. On repeating the experiment, the latter ascertained, not only that the ball could not be electrified when a needle was fastened to it, but that, when the needle was removed and the ball charged, the charge was silently and speedily withdrawn, when a point connected with the earth was presented to it. Reflecting on this, Franklin conceived the idea that pointed rods of iron fixed in the air might draw down the lightning without noise or danger.—(Franklin's Complete works, Vol. I., page 172, London, 1806).

THUNDERSTORMS.

To the purveyor of short paragraphs a thunderstorm is next only in importance to big gooseberries, inland waterspouts, and great sea serpents. At certain seasons of the year he can count on a quarter column of jottings once or twice a week, collected from provincial sources, where lightning plays wantonly, unregulated and unchecked. Evidently he regards its vagaries as something designed for the supply of news in the dull season. From north, south, east, and west the actual mischief done, or the imaginary fright occasioned, by thunderstorms and their accompanying downpours are industriously gathered for every lover of the marvellous; but never by any chance do we get an intelligent or a discriminating detail that can be called instructive. The effects of lightning are interesting to the paragraph-monger only to the extent of the damage it does, and he reckons on the damage much as a gardener reckons on the benefits of rain, as part of the order of Nature, not to be criticised, much less meddled with.

Glancing over the scores of short notices relating to thunderstorms which enliven the newspapers during the summer months, the thoughtful reader cannot fail to be struck by the mechanical and fatalistic tone in which the narratives are couched. A house here, a church there, a barn in one place, a school in another, are more or less seriously stricken, and the tale of killed or injured is the inevitable appendage. But no matter how important the building or how serious the loss of life no mention is made of the commonest precautions having been taken to avert the disaster. A universal scepticism seems to prevail as to the efficacy of all artificial precautions, or else, what amounts to the same thing, a universal superstition against adopting them. Buildings, great and small, are left to take their chance, their only safety resting on the law of averages, which, if it foredooms a few, spares the many. The fatal blow will come some day, but meanwhile apprehension is hushed in uncertainty.

Now, as regards the greater portion of the accidents to which we are alluding, there can be no question that they are preventible, and this by means both simple and inexpensive. That these means are largely neglected is a fact within everybody's knowledge, and that they are generally effectual when not neglected may be certainly inferred from the accounts of these casualties making no mention of the safeguards having failed. It is true that they do sometimes fail, and from causes which have been commented upon many times in these columns; but in the majority of cases no precautions, perfect or imperfect, have been taken, and the accident is primarily due to that fact. Of course we must except from this sweeping statement the larger public buildings and all such as properly belong to the nation. But these, when all told, make up a comparatively insignificant total, leaving an immense number of isolated and conspicuous edifices to the tender mercies of the devastating element. We include the merely isolated as well as the conspicuous, because, judging by the evidence before us, isolation is as much a danger as loftiness—a barn or a farmhouse being as frequently struck as the village steeple or the town hall.

Upon the two last-named classes of buildings some show of lightning protection is occasionally visible, but nobody ever thinks it worth while to affix such appliances to detached buildings of low structure. Yet we strongly suspect there is just as much damage done to this class of building in Great Britain as there is to similar buildings in other countries where due precaution is more general because thunderstorms are more terrific there than with us, but certainly not so frequent. The protection needed is at once so easy and so cheap that no small building should be without it; and we think its presence would be far more common in this country if the public were disabused of a prevailing error that only, or chiefly, tall buildings are exposed to the risk of being struck. We are sadly in want of trustworthy statistics relating to these matters, and the newspaper columns, for reasons referred to above, are the last places from which the figures can be drawn. But, so far as the facts are known, tall chimneys, high spires, and lofty towers are most carefully looked after, not because of their special peril—though, of course, that is considerable—but because of the special consequences that would follow their being struck; whilst by far the larger number of casualties occur to structures of meaner pretensions.

It speaks well for the system of lightning protectors at present in use that, in spite of their notorious imperfection, they do serve their purpose fairly well, flagrant cases of failure and consequent accident in spite of them being comparatively infrequent. We are glad to see this subject is being taken up in a serious spirit by electrical engineers, who alone know the conditions under which a lightning conductor may be relied upon to perform its functions faithfully. It is a subject which the law is hardly competent to touch, even if

Digitized by Google

the passing of a useful law were any longer possible for us. But public opinion may be roused to do what legislation is incapable of doing, and we should advise those whom it may concern to ply the public, first, with facts, which at this season of the year are plentiful enough, and then, secondly, with the lessons these facts teach, namely, that no building is exempt from danger where lightning is concerned, but that none need suffer if due precautions have been taken.

SIR EDWARD SABINE.

Sir Edward Sabine died at Richmond on June 26, at the age of 95. From *The Times* we learn that he was born in Dublin, October 14, 1788. His father was Mr. Joseph Sabine, of Tewin. He was educated at the Royal Military Colleges of Marlow and Woolwich, and obtained his first commission in the Artillery, December 22, 1803, receiving his captaincy in 1813. Sabine was made lieutenant-colonel in 1841, colonel ten years later, lieutenant-general in 1859, retiring with the rank of general in 1874. At a very early period of his career his interest was enlisted in physical science, and especially in the subject of terrestial magnetism. On the conclusion of the American war (1813-16), he was appointed, on the recommendation of the President and Council of the Royal Society, astronomer of the first expedition in search of the North-West passage, viz., the expedition commanded by Sir John Ross, in 1818, and on the return of that expedition, accompanied the second expedition of 1819-20, commanded by Sir Edward Parry, in the same capacity. In 1821-22 he was employed by the Government in conducting a series of pendulum experiments for determining the figure of the earth, at several stations at or near the Equator on the coasts of Africa and America, and in the following year, 1823, proceeded in the "Griper" to extend the series to Greenland, Spitzbergen, and Norway. In 1824 he was employed in publishing the results of these experiments. In 1825 he was appointed with Sir John Herschel the British members of a joint commission between the French and English Governments to determine the precise difference of longitude between the Observatories of Paris and Greenwich by means of rocket signals. In 1827 he was employed in determining by direct observation the difference in the length of the seconds pendulum at Paris and Greenwich, and of the magnetic force of the earth at the same stations. For many years after this, in order to verify his theories and complete his knowledge, he himself carried on a vast series of observations, both in terrestrial magnetism and on the acceleration of the pendulum in different latitudes in all parts of the globe, from the Equator to Arctic Circle. The results of these observations and of the experiments he made at the Royal Observatory and elsewhere were regularly communicated to the Royal Society and to the British Association, and gave a great impulse to systematic observations in these directions. In 1822 he gave the Bakerian Lecture of the Royal Society, "On the experiments to determine the amount of dip of the magnetic needle in London in 1821." In 1836 and 1837 he presented to the British Association an account of a magnetic survey of the British Islands and a report of the variations of the magnetic force in different parts of the globe. Again, in 1840, he still deals with the great subject of terrestrial magnetism, extending and giving precision to our knowledge of the vastly important question of the lines of declination and intensity on the surface of the earth. Thirty-two years later Sabine was working in the same direction, and in 1872 we find him bringing before the Royal Society his thirteenth contribution on the subject of terrestrial magnetism. A moment's thought will show the vast practical importance of such experiments. An accurate knowledge of the lines of intensity, of dip and inclination of terrestrial magnetism, ever shifting, even though slowly, is of the highest moment to all whose safety depends on the indications of the mariner's compass. Not, probably, that Sabine had any distinct idea of simply benefiting navigation by his researches; this is one of those instances of scientific research pursued for its own sake, from the mere desire of adding to an accurate knowledge of the multifarious phenomena of our wonderful universe, but which almost inevitably involves results of high practical value to humanity. In his report for 1838 Sabine concludes:—

"Viewed in itself and its various relations, the magnetism of the earth cannot be counted less than one of the most important branches of the physical history of the planet we inhabit; and we may feel quite assured that the completion of our knowledge of its distribution on the surface of the earth would be regarded by our contemporaries and by posterity as a fitting enterprise of a maritime people, and a worthy achievement of a nation which has ever sought to rank foremost in every arduous and honourable undertaking."

An immediate result of this report was that Captain James Ross was sent in command of the "Erebus" and "Terror" to make a magnetic survey of the Antarctic regions, and to plant on his way three magnetical and meteorological observatories at St. Helena, the Cape, and Van Diemen's Land. Not only so, but this and his other valuable reports gave rise to a series of observations in all our colonies and all over the globe as well as at home, the results of which completely changed the aspect of this vast department of science. The colonial observatories were for many years under the guidance of Sabine; and he reduced and published the results obtained at them as well as those of a general magnetic survey of the globe begun at that period under the directions of the Admiralty. Indeed, the firm foundations on which the science of terrestrial magnetism are now based, and the vast advances it has made in recent years, may be mainly attributed to Sabine's exertions. Sabine was elected to the Royal Society in 1818, was vice-president in 1850, and succeeded the late Sir Benjamin Brodie in the presidency in 1861. He held the latter post till 1871, when he lost his accomplished and congenial wife, whom he had married upwards of half a century before. She herself was the translator of Humboldt's "Cosmos," which Sir Edward edited in 1849-58. He was for many years an active member of the British Association, at whose meetings some of his most important papers were read, was its general secretary twenty-one years, and the presidential chair of which he filled in 1853. He was a member of the Royal Commission to inquire into the standard of weights and measures (1868), and was made a K.C.B. in 1869. He had the Prussian order *pour le mérite*, the Italian of Ss. Maurice and Lazaro, and the Brazilian of the Rose. In 1821 he received the Copley medal of the Royal Society; in 1826 the Lalande medal of the Institute of France; and in 1849 the Royal medal of the Royal Society. He was elected honorary or corresponding member of many of the principal academies and societies of Europe and America. As a scientific worker Sir Edward Sabine holds a high rank, and his name will ever hold a large place in the annals of science and the history of navigation.

WILLIAM SPOTTISWOODE.

On the day following the death of Sir Edward Sabine we were discussing the then dangerous condition of the President of the Royal Society. It must have been during the hour of our conversation that one of the brightest scientific lights that has adorned this or any other country passed away. A remark made by the gentleman with whom we were conversing concerning the critical condition of Mr. Spottiswoode will be accepted almost as a truism:—"His great services to science and to scientific men will not be realised till he is gone." Only those who knew him intimately knew his strength—knew how quietly and how unostentatiously he was accustomed to open his stores of knowledge for all who came to him for help. He seemed delighted if he could give pleasure, not only to his scientific friends, but to all with whom he was brought into contact. We are indebted to *The Times* for the facts in the following remarks:—The death of a President of the Royal Society in his term

Digitized by Google

of office—especially since that became limited—has been rare indeed. True, both Newton and Banks died in their presidential chairs, but the former had filled the office for twenty-four and the latter for forty-two years. Mr. Spottiswoode was elected only four years ago. He was the type of a student of science almost peculiar to this country, one who does not follow science as a vocation, but as an avocation, who cultivates it from pure love in the leisure left him by the busy life of a man of business or affairs. We have had several notable examples of this class of investigator, but among living men we need only mention the names of Sir John Lubbock and Mr. De La Rue. Such men have done substantial service to science, and none more than the late President of the Royal Society, although in fields which are in the main accessible only to the esoteric few. But these services are none the less momentous or far-reaching on this account; they deal with the deepest principles which underlie all physical research. William Spottiswoode belonged to a very old Scottish family, which has produced several notable men since the time of the Archbishop of St. Andrews in the sixteenth and seventeenth centuries, while a branch of it has achieved in some of its members considerable prominence in the United States. He was born in London on January 11, 1825, son of Andrew Spottiswoode, brother to the Laird of Spottiswoode, and the then head of the printing business. After spending some time at Laleham at a school kept by Mr. Buckland, brother of Dean Buckland, and a severe disciplinarian, young Spottiswoode was sent to Eton, where, however, he stayed only a short time; he and his brother attempted some chemical experiments (in which detonation played a prominent part) at a time when science had no place in our public schools. No blame, however, it is admitted, was attached to the brothers, who were transferred to Harrow, then under the rule of the present Bishop of London. Here William Spottiswoode had the reputation of being studious and thoughtful, and, after a stay of three years, entered Balliol College, Oxford, in 1842, having obtained at Harrow a Lyon Scholarship. In 1845 Spottiswoode took a first-class in mathematics, winning in 1846 the Junior and in 1847 the Senior University Mathematical Scholarship. Although on quitting college he entered upon the active management of the business of the Queen's Printers, resigned to him by his father, still he gave lectures for a term or two at Balliol, and ten years later was examiner in the Mathematical schools. Mr. Spottiswoode was nearly as good a linguist as he was a mathematician, and so accomplished an Oriental scholar was he that he was urged to undertake an edition of a great work on Indian astronomy, on which he contributed a paper to the *Journal* of the Asiatic Society. During the thirty-five years that have elapsed since Mr. Spottiswoode left college, his life has been an unusually busy one. Mr. Spottiswoode's earliest scientific work consisted of five quarto pamphlets, published in 1847, under the title of "Meditationes Analyticæ," and since then scarcely a year has passed without a contribution from him to one or other of the branches of science in which he was interested. Many of these papers, as we have said, appeal only to specialists, and deal with abstruse mathematics; but in these, as in his more purely physical work, fellow-students, both in this country and abroad, admit he showed an intellect not only of the the highest training, but of rare clearness, penetration, and even originality. No one had an easier familiarity with the mysterious symbols of the modern mathematician, and some of the methods originated by him have become classical. Spottiswoode has been called the "incarnation of symmetry," and this feature of his mind comes out not only in his mathematical work, but in those beautiful researches in physics connected with polarised light and certain forms of electrical discharge with which his name is intimately associated. Indeed, his researches in these departments have in some respects all the merit of originality, and especially in connection with the exquisite phenomenon of polarisation his work, both as an investigator and expounder, takes the highest rank. It goes without saying that honours were showered upon Mr. Spottiswoode; our leading universities enrolled him among their "doctors," the Paris Academy of Sciences made him a corresponding member, while other foreign societies gave similar evidence of the estimate in which they held him. Finally, in 1879, he was chosen to the highest honour which science in this country has to bestow—the presidency of the Royal Society. Here he filled a position of no small difficulty with the greatest tact. His annual addresses were models of what such productions should be, while his beautiful country seat at Sevenoaks was famous on both Continents for its cultured hospitality. Mr. Spottiswoode's relations with the workmen in his large establishment were of the best and friendliest, and these will feel that in him they have lost a real friend. Thus, as we have said, his death will be felt as a grievous loss in many quarters, most of all among that wide circle to whom he was endeared as a true and ever-sympathetic friend. In 1861 he married the eldest daughter of the late Mr. William Urquhart Arbuthnot, a distinguished member of the Indian Council. He died at the early age of fifty-eight of an attack of typhoid fever.

CORRESPONDENCE.

ELECTRIC RAILWAY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As that system of electric locomotion in which the rails are utilised as conductors appears to be increasing in favour, perhaps the following might be applied to advantage by some enterprising electrician:—

In driving a current through a great length of rail, it is obvious that a large amount of energy is lost, not only from leakage attendant on imperfect insulation, but also from humidity and corrosion. In order to meet these difficulties it has already been suggested to send the current automatically through only one portion of the rail at a time, but as this suggestion does not appear to have been practically applied to any great extent, I submit the following scheme to your notice, should you think it worthy of appearing in your invaluable columns:—

FIG. 1

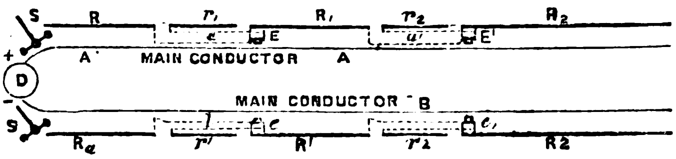

FIG. 2

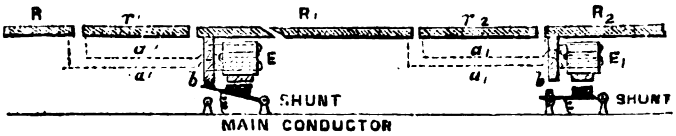


Let the rails be divided into sections such as R R_1 R_2 r_1 r_2 (Fig. 1). The current is conveyed by two insulated conductors, A_1 B_1, placed between the rails. Supposing a locomotive to be on section R R_a, the current is shunted—by means of a hand shunt S—from the conductor A to R, through the wheels of the engine to the motor, thence to R_a and through S_1 to the conductor B. The engine will now move forward to section r_1 r^1, and the current will now flow from R_1 through an auxiliary conductor a, round an electro-magnet E, entering r at y, thence through the motor to r^1, through another auxiliary conductor l, round an electro-magnet e, thence through R_a back to the dynamo. But in flowing round E the current magnetises it, and the electro-magnet attracts a shunt, connected to the main conductor A, which makes contact at b (Fig. 2) with the rail R_1. A similar arrangement connects R^1 with B.

The moment the locomotive reaches R_1 R^1, the sections R R_a $r_1 r^1$ are disconnected, and, on closing the shunt S, are completely cut out of the circuit. But, as communication is now established between R_1 and R^1, a current will still flow round the electro-magnets E e, although through a different

circuit, and retain the contact already made between the shunts and the sections R_1 R^1. As the locomotive proceeds it will in time reach r_2r'', another pair of electro-magnets and shunts will put R_2R'' into communication with the conductors; the sections R_1R^1 are retained in the circuit until R_2R'' are reached, and then they are cut out as well as the subsections r_2r''.

The object of the smaller sections r_1r_2, &c., and the auxiliary conductors, is to produce sufficient magnetism in the electro-magnets to help the shunts in contact with the major sections, until the locomotive, having reached these, and thus completed the circuit, shunts a portion of its current round the electro-magnets.

One objection to this system might be, that the trains could only travel in one direction on the same line, owing to the automatic arrangement, but this could be easily remedied by using a return line.—Yours, &c., JOHN TOURTEL.

32, Springfield-place, Leeds, June 12, 1883.

ON THE WINDING OF ELECTRO-MAGNETS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Professors Ayrton and Perry having directed their experiments towards the discovery of the best mode of winding a given length of wire on an iron bar to give the strongest electro-magnet for the same current, have just supplied me with part of the information of which I have been in search. We pigmies in electrical erudition are apt to take it for granted that the giants (such as the above mentioned professors) have already discovered and are familiar with all the laws and rules which should govern electricians in the most advantageous construction of instruments, and sometimes we suppose that it is only due to our comparative ignorance that we are unacquainted with these rules.

Curious to say, I had noted with other plans of winding electro-magnets those mentioned by Professors Ayrton and Perry in *Phil. Mag.* for this month, or rather I had noted the desirability of investigating the respective effects of winding so as to give the electro-magnet the form (nearly) of (i) an hour-glass and (ii) of an egg. Something in the construction of some noted induction coils led me to believe that this question has already been investigated, but as I could not find any published account of the laws regulating these effects, I was anxious to find them out for myself.

I am also desirous of investigating the effect of winding in another manner, which appears advantageous.

Suppose that the reel of an electro-magnet will hold 40 turns of wire of a particular gauge in each layer. I propose, instead of winding one wire 40 times in each layer, to take 40 wires, and wind them, side by side, until the reel is full, bringing out the 40 inside ends through a slit in the core. It is obvious that the 80 ends may be joined up in many ways, so as to vary the resistance of the electro-magnet, and if the 40 wires are joined up in parallel circuit, the resistance will be enormously reduced. For example, a coil which, wound in the ordinary way, has a resistance of 400 ohms, may be wound so as to have 40 parallel circuits of 10 ohms each, and (following the law that the joint resistance of any number of wires joined parallel to one another is equal to the reciprocal of the sum of the reciprocals of their respective resistences) their joint resistance will be only ·25 ohm, instead of 400 as when connected in series, whereas the current passing through any one of them will be the same as in series. As the curve at passing through any turn of wire in the coil will be the same in both cases, I conclude that the magnetic effect will also be the same, whereas the total resistance of the coil may be enormously reduced.

As the resistance of an electro-magnet should always bear a certain proportion to the total resistance in circuit in order to obtain the maximum effect, it would appear that the above means of varying the resistance of the electro-magnet for the various resistances of different circuits may be applied with good effect. In telegraph instruments, Mr. R. Sabine has shown that the speed of transmission diminishes with the resistance in circuit, and that the resistance of the receiving instrument has a great influence on the speed, so that it would seem that this plan of reducing resistance might be adopted with advantage, especially where there are a number of electro-magnets in circuit. I propose also to try the effect of variation in gauge of the wires near the poles and towards the neutral line of the magnet. This mode of winding, in fact, will suggest an endless variety of combinations in joining up the wires, so that the resistance may be varied within a very wide range, to say nothing of differential and partly differential methods. I write this with some diffidence, as I may have made some gigantic error in principle, so I shall only sign myself, yours, &c., CACARUCAS.

MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not think that Mr. Bennett, p. 109, would be at all "trespassing on your valuable space if he attempted to demonstrate the physiological actions" of electricity. For my own part, I quite hold with him that *electricity*, either continuous or alternating, has powerful medical action, though *magnetism* has little or none. That is where the difference comes in. In one case there is a supply of energy directed upon the nerves and tissues; in the other case the action, if any, is merely an obstruction to the internal energies of the body itself. I used to think that I knew a good deal about medical electricity, but my estimate has resembled a condenser charge, constantly lowering. Unfortunately, the whole subject has been too much left in the hands of quacks and of a few medical men who have made it a speciality, and it is difficult to obtain any reliable scientific information.

There is the subject of intermittent, or coil, currents. Can Mr. Bennett give real information as to their action? I have had a growing conviction that it is not an electric action at all, but what may be called an internal friction, a muscular exercise set up by the contractions and relaxes resulting from the successive electric charges. Now this is very important, as it would dispose of a great deal of mysticism, and make coil construction and use a very simple matter.—Yours, &c.

J. T. SPRAGUE.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having completed the experiments promised in my last, I have now the pleasure of sending the results to you. I will number the conductors as before.

The chimney head on which No. 1 is fixed was under repair last week. While that was proceeding I took the opportunity to make a test of the conductor from spear to earth. For this purpose an insulated No. 16 copper wire, which I will call l_3, was taken to the top and fastened to the spear, about the middle, after filing a bright surface thereon. The other end was in connection with the terminal of the Wheatstone bridge. Previous to fixing this wire, its resistance was measured and found to be ·53 ohm. One of the wires hitherto used for testing the earth of this conductor, which I may call l_1—using the same letters as "A. J." in your issue of last week—is soldered at a height of 125·5ft. from the top, measures 22·5ft., and has a resistance of ·0697, say ·07 ohm. The wire to the main water earth l_2 measures 11ft., and has a resistance of ·03399, say ·03 ohm. All the wires were insulated. The battery consisted of four Leclanché cells, and the galvanometer had coils of 2, 10, and 1,000 ohms resistance. Ten ohms gave the best indication. The resistances of the leading wires were thus:—

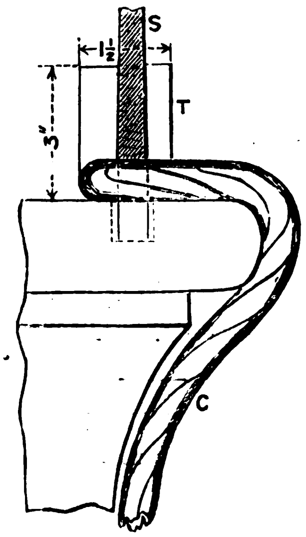
l_1 = ·07 ohm.
l_2 = ·03 „
l_3 = ·53 „

The instruments, &c., being ready the first test was made with the + current passing from bridge through l_3 to spear, and back through conductor, earth, and leading wire l_2. I got a resistance of 1·75 ohm, less $l_3 + l_2$ = 1·19 ohm. The

Digitized by Google

second test was made through l_3, spear, conductor, and l_1, without earth, when I got 1·54, less $l_3 + l_1$ = ·94 ohm. The third test showed the resistance of the earth and that part of the conductor below l_1, taken through l_1, conductor, earth, and l_2, to be ·27, less $l_1 + l_2$ = ·17 ohm net.

By the first test the conductor has a resistance of 1·19 — ·17 = 1·02 ohm, and by the second it is ·94 ohm. The earth resistance is nearly the same as when last tested. Calculating the resistance of 126·5ft. of ⅝in. conductor (the length in circuit), composed of seven wires of No. 11B. W.G., I find it to be about ·01446 ohm for pure copper; and the mean of the resistances found above is about 68 times greater. This indicates a fault somewhere, the most likely place being the junction of the copper rope with the spear. I questioned the man working at the top as to how the fastening was made, and found that the spear was let in to the stone cope for some distance, and run up with lead. The copper rope was then put once round, and the free end spliced into the rope in the form of a loop. I felt that this joint should be made good, but was somewhat at a loss to know how to do it. Ultimately I hit upon the following plan :—A thin piece of sheet copper was bent into the form of a tube 1½in. diameter and 3in. high. A piece was cut out of the side to bridge over the conductor, and the inside was tinned. The lower end of the spear and loop of the conductor were then polished with a file and emery cloth, and the copper tube placed in position. The bottom and side joints



were now packed with a bit of soft clay. S the spear, T the tube, and C the conductor, in the sketch, illustrate the arrangement.

At this stage I tested the conductor again, more out of curiosity than otherwise, and found that the resistance had increased to 17·1 ohms. I thought the man had altered or loosened the testing wire on the spear, and made him re-adjust it without altering the resistance, so I concluded that in cleaning the loop he had broken part of the slight connection which must have existed between spear and conductor, and so it proved to be. A pot of molten lead was now sent up, and some resin. The latter was put into the tube first, after it the lead. When the first ladleful was poured in I depressed the keys, and found the resistance had fallen to ·80 ohm through l_3, spear, conductor, and l_1.

On the completion of the operation I tested the conductor carefully, with the current flowing as before through the same leading wires, and got the following result, viz.:—

Conductor and earth ·80 — ·56 = ·24 ohm.
Conductor alone ·64 — ·60 = ·04 ohm.
Earth alone ·29 — ·10 = ·19 ohm.
Conductor + earth ·04 + ·19 = ·23 ohm.

The lead joint had therefore reduced the resistance from 68 to 2¾ times that of pure copper; 2¾ is still very high, but several considerations lead one to expect the resistance to be greater than the calculated one. Besides impurities in the copper, the strands are very much thinned by oxydation and 25 years' exposure to the weather. Oxydation has also insulated the wires from each other; so that the testing wire l_1 which was soldered to the outside strands is not likely to be in metallic contact with the central one, thus throwing it out of circuit. There is also the probability that a wire may be broken, although such was not noticed. For these reasons I am inclined to believe that the result of this test is satisfactory.

With regard to the conductors Nos. 2 and 3, I have tested these again, partly under the conditions suggested by your correspondent "A. J." The battery was the same as that used with No. 1, but the leading wires were different. The latter had a combined resistance of ·98 ohm. The galvanometer indicated a difference in both conductors where the poles were reversed. For No. 2 I got with the + current to bridge 1·44 ohm, and with the — current 1·60, mean 1·52 ohm. 1·52 — ·98 = ·54 ohm is, therefore, the earth resistance of this conductor. With No. 3 the + current to bridge gave 1·13; and the — current 1·33, mean 1·23 ohm. 1·23 — ·98 = ·25 ohm for the earth of No. 3.

I may add with reference to the earths of Nos. 1 and 3 conductors that I had the impression that the water pipes to which they are fixed were separate and distinct from the main water supply of the town. But I now find that, although the pipes are worked as different systems, I have overlooked the fact that they are more or less metallically connected through apparatus in the works. The main water pipe was not, therefore, a proper battery earth with which to test them. I have tried the gas pipes, but they also give low resistances, and I feel sure they are in metallic connection with the water systems, and short circuiting somewhere. I must therefore make new tests with artificial earths made with copper plates.

No. 2 is earthed to an iron pipe in an old deep well, not in use, and not in contact with the other water systems, so far as I am aware. The distance from l_1 to the well is 113ft., and there are two soldered splices included in the circuit, but this difference will hardly account for the much greater resistance of this conductor earth. It appears to be due rather to the fact that it is not in metallic connection with the other two, and, therefore, a truer earth.—Yours, &c.,

Greenock, June 26, 1883. T. L. P.

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The experiment made by Dr. Higgs with a Schuckert machine, in describing which he states that he obtained nearly the normal E.M.F. when exciting from one side only of the ring, entirely agrees with the remarks I made in a letter to you of recent date.

Dr. Higgs's experiment would tend to prove that if the core of the ring can be *saturated* by induction from magnets on one side only, the E.M.F. for a given speed is practically at a maximum for that particular ring, which is precisely what I intended to convey.

My chief reason for writing to you now is that Mr. Mordey has attained such different results in his repetition of the experiment. That he should obtain but 1 per cent. of the normal E.M.F. when using one pair of magnets is, I consider, a most extraordinary result, and I for one should be glad to have further particulars of the experiment, if Mr. Mordey will favour us with them.

The only explanation I can imagine for such a result is that Mr. Mordey had all the field magnets *in position*, when *exciting* one pair only; if so, of course, the armature was magnetically short circuited by the idle pair.—Yours, &c.,

Cambridge-street Works, Birmingham, June 27, 1883. W. B. SAYERS.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts for the week ending 15th June, 1883, were £1,490, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

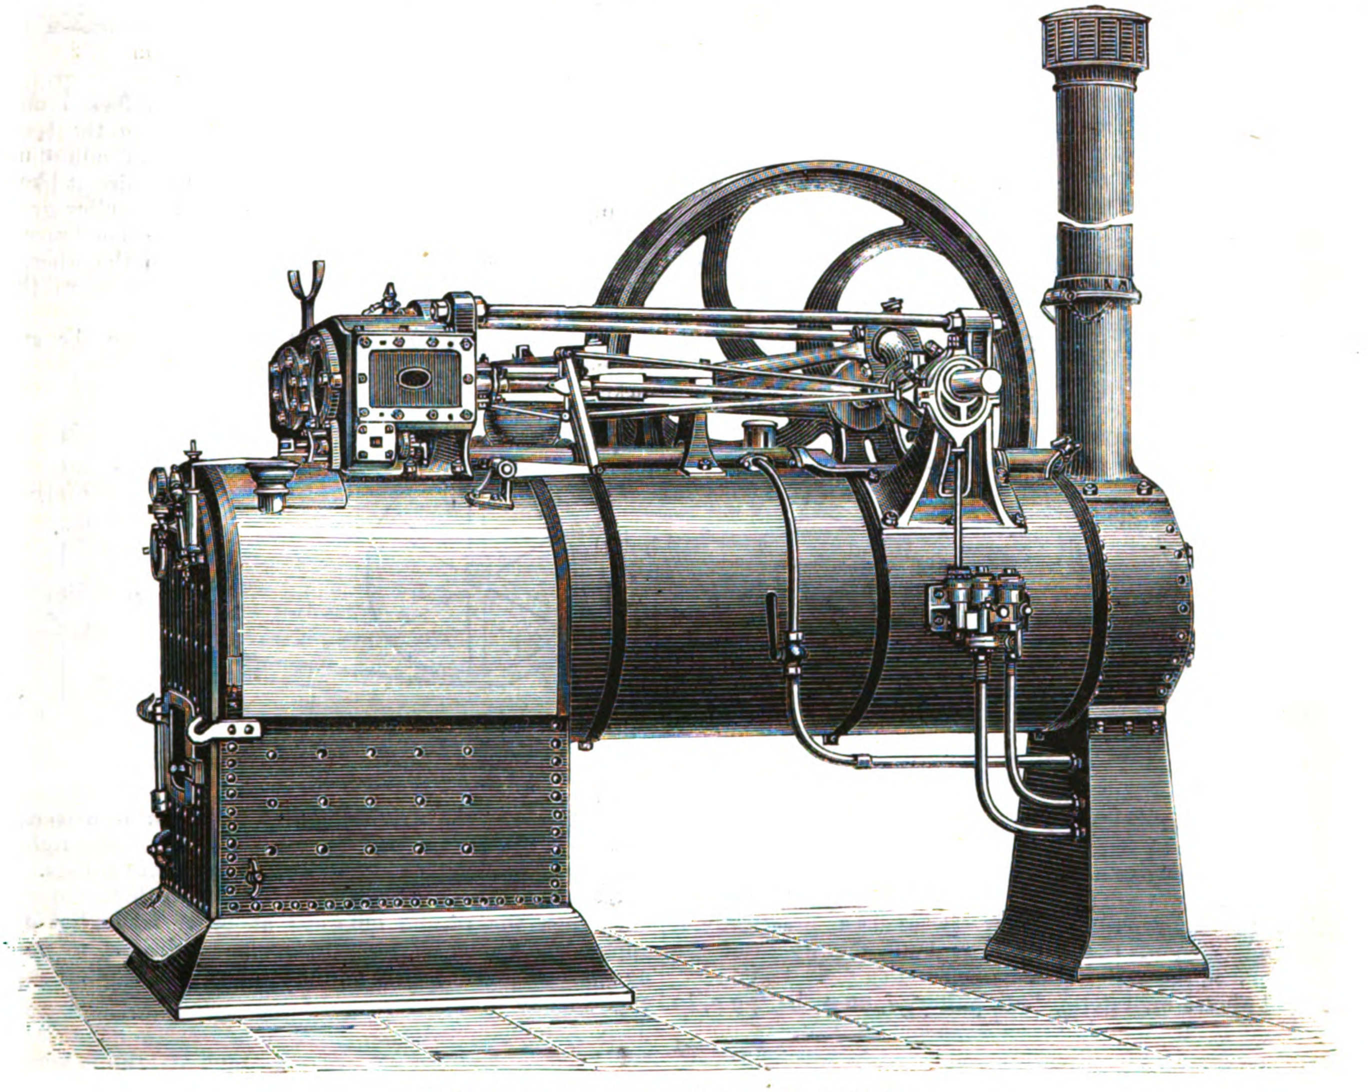
THE HOLBORN RESTAURANT INSTALLATION.

We have already referred to this installation of the Edison system, and herewith give, with illustrations, a somewhat more detailed account of the machine room. The want of space has interfered with the arrangement, which would no doubt have been different had the accommodation been ampler. Two semi-portable engines, of 16 horse-power each, by Messrs. Ransomes, Head, and Jefferies, of Ipswich, are used to drive the Edison dynamos. The two engines are placed side by side. Our illustration shows one of the engines. They each have two $9\frac{3}{8}$in. cylinders with a 12in. stroke, and the speed is 140 revolutions per minute. Each is fitted with Ransomes' patent automatic governor expansion gear, which we have more than once described. In this arrangement the governor acts directly upon the expansion slide valve by means of a link motion, and its action is to admit steam to the cylinder at full boiler pressure in proportion to the work on the engine. The results obtained with this gear in electric light work have been satisfactory. At some trials made at the South Kensington Museum with a similar engine the coal consumption was found to be 2·74lbs. per hour per indicated horse-power, a good result for high-pressure engines.



Ransome's Engine—Holborn Restaurant Installation.

There is on trial at this installation one of Samper's Pulley-Grippers, for the following description of which we are indebted to Mr. M. F. Adams, the representative of Mr. Samper in England. The object of this invention is to increase the adhesion of the cords or belts employed for the transmission of motion, avoiding or nullifying the tension between the intermediate shafts, and guiding the cords or belts accurately. By the ordinary system the cords or belts embrace only half the circumference of the pulleys if these are of equal size, and less than half of one of them if they are unequal; but since the vibration of the belts while running causes them to lose their grip on a portion of the circumference embraced, it results that the adhesion is much less in practice than is expected, and in the majority of cases, being insufficient for the transmission of power, recourse has hitherto been had to two methods for establishing the adhesion and for supplying the want of points of contact between the cords or belts and the pulleys. These two methods are:—(1) keeping the belts very short, and consequently tight; or (2) producing this same tension by means of a loose pulley called a "Belt-Tightener," which derives its name from its use. The imperfection of these two methods of producing adhesion originates many evils, such as the heating and destruction of the intermediate shafts, of the bearings, and of the belts, loss of power, waste of fuel, stoppage of operations, and impossibility of turning angles, &c. It is these defects and inconveniences that Mr. Samper proposes to remedy and prevent by means of his system. By the above-mentioned methods, hitherto employed for producing tension, not only is the desired rotary motion imparted to the shafts, but they are also subjected to a lateral strain, whilst Mr. Samper claims that in his system the rotary motion alone is produced without deflecting the shafts. The patentee employs a loose "pulley-gripper," which is flanged, while the intermediate pulleys are not. The pulley-gripper is mounted on one or two arms independent of the intermediate shafts, or else on arms which are fitted on the shaft itself, but loose, and secured between collars.

Digitized by Google

By one of these two general methods this system can be applied in all existing cases. The "following" side of the cord or belt is picked up by the pulley-gripper, which is brought up close to the intermediate pulley, touching it if desired, but not pressing against it, and is then moved along

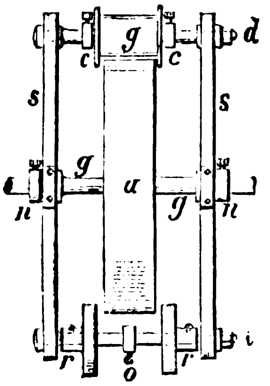


FIG. 1.

a circumference concentric with that of the pulley until it nearly brings into contact the "following" and "leading" sides of the belt, and in this manner the cord or belt embraces nearly the whole circumference of the pulley. By these means the *contact* of the belt or cord with the which has been applied a pulley-gripper, *g*, fitted on the arms *s s*. These arms are fixed loose on the shaft *g g*, and are held in position and kept from rubbing against the pulley by means of the collars *n n*. The arms *s s* are adjusted by means of two spindles, *d i*, which have on each end two washers and one nut. The pulley-gripper *g* has flanges for guiding the belt, and is kept face to face with the pulley, or in whatever position may be desired, by means of the collars *c c*.

The pieces *r r* on the spindle *i* are for guiding the belt, in case the apparatus is used for stopping the motion, in order that when the pulley-gripper is drawn away, and the belt falls slack, it may not come off the intermediate pulley. These pieces need not be rotary, and are useless when the apparatus is not required for stopping the motion, or when the arms of the pulley-gripper are in close proximity to the pulley. The hook *o* is for hanging a weight to support the apparatus, or for attaching a cord to fix or tighten it, if required.

Fig. 2 shows an arrangement in which the pulley-gripper *g* is placed so as to cause the greatest possible adhesion on the pulley *a*, and the pulley-gripper *g* is regulating the tension of the belt without obtaining the maximum of adhesion on the pulley *x*, because this pulley does not require it like the other. On the pulley *a*, the flanges of the pulley-gripper face the pulley, and on the pulley *x* the flanges embrace the pulley, because the pulley *x* is narrower than the other, and by that means a belt can be used the entire width of pulley *x*.

Fig. 3 shows an arrangement for increasing the speed.

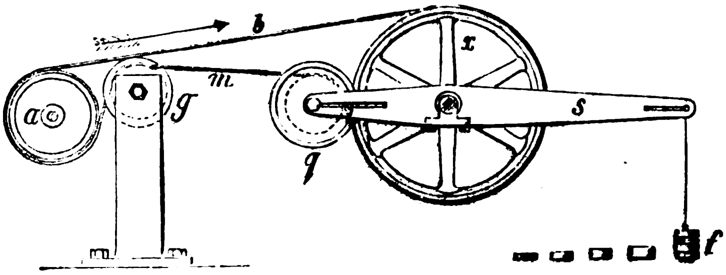

FIG. 2.

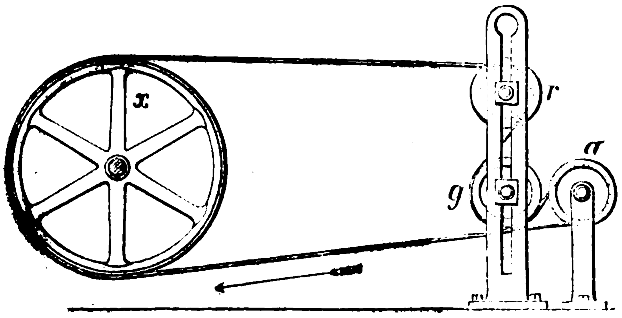

FIG. 3.

driving pulley is increased from the ordinary average of 180° to as much as 325°, thus causing the adhesion of the belt to the pulley to a point far beyond the centre of the shafts, and as the pulley-gripper is always kept close against the intermediate pulley, it secures practically a steady adhesion of the belt throughout the whole of the circumference theoretically embraced.

Fig. 1 shows an intermediate pulley, *a*, on a shaft, *g g*, to

The pulley *x* is the driving pulley, pulley *a* is driven; the roller *g* is the pulley-gripper, and the roller *r* is a tightener running in the vertical slot of the arms of both rollers.

We have witnessed a series of trials with this gripper, and have seen the results obtained at other trials, but as the apparatus is to be tried under various conditions, we need do no more at present than call the attention of electric light engineers to it.

THE DISCOVERY OF THE ELECTRIC LIGHT.

Professor Silvanus P. Thompson writes under the heading of "Historic Notes on Physics" in *Nature*:—"In looking through an old volume of the *Journal de Paris*, I came across the following entry, for the date 22 Ventôse, An X. (March 12, 1802), which clearly relates to an exhibition of the electric arc light:—

"'Le citoyen Robertson, auteur de la phantasmagorie, fait dans ce moment, des expériences intéressantes, et qui doivent sans doute avancer nos connoissances sur le *galvanisme*. Il vient de monter des piles métalliques, au nombre de 2,500 plaques de zinc, et autant en cuivre rosette. Nous parlerons incessament de ses résultats, aussi que d'une expérience nouvelle qu'il a faite hier avec deux charbons ardens. Le premier étant placé à la base d'une colonne de 120 élémens de zinc et argent, et le second communiquant avec le sommet de la pile, ils ont donné, au moment de leur réunion, une étincelle brillante, d'eune extrême blancheur, qui a été apperçue par toute la société. Le citoyen Robertson répétera cette expérience le 25.'

"The individual who thus came before the public was named Etienne Gaspard Robertson, a name suggestive of Scotch descent. He was better known for his 'Phantasmagoria,' exhibited a few years later in London. Of this invention a notice appears earlier in the volume from which the above passage is taken; and in an earlier volume of the *Journal de Paris* in the month '*Fructidor*, An VIII.,' there occurs a mention of some of his experiments on the *couronne de tasses* of Volta.

"It is worthy of casual notice that in the number where Robertson's 'Phantasmagoria' is advertised, the very next advertisement on the page is one of an exhibition to be given by Citoyen Martin at the Hôtel de Fermes, wherein, as part of a

Digitized by Google

'spectacle extraordinaire et amusant de Physique,' &c., was to be shown 'l'expérience du télégraphie plus rapide que la lumière d'un effet extraordinaire et amusant.'

"The usual date given for the invention of the electric light by Sir Humphry Davy is 1809, but I was aware that earlier notices existed both in Cuthbertson's 'Electricity' (1807) and other works. I was also under the impression that some earlier reference to the matter existed in Davy's own works. The finding of this notice in the *Journal de Paris* induced me to consult the early volumes of the *Philosophical Magazine* and of *Nicholson's Journal*.

"In the *Philosophical Magazine*, Vol. IX., p. 219, under the date February 1, 1801, the following passage occurs in a paper by H. Moyes, of Edinburgh, in which experiments with a voltaic pile or column are described :—

"'When the above column was at the height of its strength its sparks were seen in the light of the day, even when taken with a piece of charcoal held in the hand.'

"In the *Journal of the Royal Institution*, Vol. I. (1802), Davy describes (p. 106) some experiments on the spark yielded by the pile, and states : 'When, instead of the metals, pieces of well burned charcoal were employed, the spark was still larger and of a vivid whiteness.' On p. 214 he describes and depicts an 'apparatus for taking the galvano-electrical spark in fluids and aëriform substances.' This apparatus consisted of a glass tube open at the top and having a tubulure at the side through which a wire, tipped with charcoal, was introduced, another wire, also tipped with charcoal, being cemented in a vertical position through the bottom.

"But earlier than any of these is a letter printed at p. 150 of *Nicholson's Journal* for October, 1800. This letter is entitled 'Additional Experiments in Galvanic Electricity, in a letter to Mr. Nicholson.' It is dated 'Dowry-square, Hotwells, September 22, 1800,' and is signed by Humphry Davy, who at that time was assistant to Dr. Beddoes at the old Philosophical Institution in Bristol. The letter begins thus :—

"'Sir: The earlier experimenters on animal electricity noticed the power of well-burned charcoal to conduct the common galvanic influence. I have found that this substance possesses the same properties as metallic bodies in producing the shock and spark*, when made a medium of communication between the ends of the galvanic pile of Signor Volta.'

"In none of these extracts, however, is anything said of the properties of the *arc* as a *continuous* luminous spark. These were made known in Davy's later researches. Yet the electric light attracted attention, as we see, before the special property of continuity was observed."

* Here Davy adds a foot-note : "The spark is most vivid when the charcoal is hot."

ELECTRICITY v. GAS AT THE SOUTH WALES WORKS.

[The following correspondence from a local contemporary is so very interesting, and the facts stated of so practical a nature, that the wider the publicity obtained the better for the success of electric lighting.—Ed. *E.*]

TO THE EDITOR OF THE LLANELLY AND COUNTY GUARDIAN.

Dear Sir: In reference to the paragraph appearing in your issue of last week with regard to the electric lighting at the South Wales Tinplate Works, might I ask you to find room when you next go to press for the following report which I have received from Messrs. Morewood and Co.—Your faithfully, Jno. C. Howell.

[Copy.]

"South Wales Steel, Iron, and Tinplate Works,
"Llanelly, June 7th, 1883.

"J. C. Howell, Esq., Llanelly.

"Dear Sir: I am sorry to hear that a report has been spread to the effect that the electric light was not successful in our works, and this morning I was surprised to learn that it was rumoured that we contemplated returning to gas.

"I feel it only fair to yourself and Messrs Crompton and Co. to contradict these statements, and to give you some information respecting our experience of the incandescence electric light plant supplied to us by Messrs. Crompton, and you are at liberty to make what use you think well of such information.

"We started the first installation of fifty lamps on November 1st, and after about a month's trial were so satisfied with it both as to cost and the superior quality of the light as compared with gas, that we ordered a second dynamo machine, cables, &c., which we started about the middle of January, giving us a total of one hundred lamps. Since then they have been working regularly every night except, of course, Saturday and Sunday nights, and during the last two months twenty of the lamps have not been required, as the days are now so long. Our two assorting rooms, tin houses, annealing and pickling rooms, cold roll room, and to some extent our mills, are lighted by the electric light, and the only trouble that we have had in any department has been in the tin houses, where we find the dust from the bran and the smoke from the grease pots collect upon the lamps, which have to be wiped off almost every evening. I have little doubt that this can be overcome by suitable glass covers, but even if it cannot be, the expense of wiping the lamps in the tin house is so small as to be of no importance.

"Some may naturally ask you why we have not put up the electric light in our iron forge and steel works. We shall ultimately do so, but the life of iron is so uncertain, and if we convert our iron forge into an extension of our steel works, or use it for other purposes, the alterations might entail new arrangements of the lamps. Besides this we make our own gas, and very naturally do not like to discontinue the use of the retorts until they are worn out, but we certainly shall not renew them.

"As to the comparative cost of the electric light and gas, there can be no question that for an equal candle-power the electric light is the cheaper if we pay 3s. 9d. a 1,000 cubic feet for gas ; and even when making one's own gas, as we do, I am doubtful whether the electric light is not the more economical of the two, in addition to which we have a superior quality of light.

"Six months' experience is too short a time to enable me to give anything but an estimate of the cost of electric lighting, as some parts of the machines only require renewing once in every two or three years. In fact, as yet the cost of renewals has been almost nothing, except in lamps. I, however, estimate that over a series of years this item of expense will not exceed £60 per annum for 100 lights, exclusive of lamps, and this is confirmed by the reports of others, who say that 10 per cent. upon the cost of the plant will quite cover repairs, and £60 is a great deal in excess of 10 per cent. upon the cost of our plant. Taking this sum as the expenditure on repairs, the cost of the electric light will be as follows in cases similar to our own, where there is spare steam at night :

	£	s.	d.
Wages	62	0	0
Lamps	90	0	0
Repairs, &c.	60	0	0
Oil and stores	13	0	0
	225	0	0
Less work done by engineer	41	6	8
	£183	13	4

I deduct the above amount for the work done by the engineer. He has nothing to do except to oil the bearings once or twice during the night, and can turn rolls, screws for the mills, &c., in a lathe driven by the same engine as the dynamos ; in fact, it is an advantage in more ways than one to give him this work to do, as it prevents him from going to sleep and so neglecting oiling the machinery, as well as the saving in wages.

"This cost is for 100 lamps of 17 candle-power for a year, using them on an average five nights a week for 14 hours in the winter six months, and nine hours in the summer six months; this gives a total of 2,990 hours, during the whole of which we have 1,700 candle-power of light for the sum of £183 13s. 4d.

Digitized by Google

"What would an equal light cost in gas at 3s. 9d. a 1,000 cubic feet? We cannot calculate on burning less than one cubic foot of gas per hour for every three candles'-power; so to get 1,700 candle-power for 2,990 hours, we should burn 1,694,300 cubic feet of gas, costing £317 14s. 7d., against £183 13s. 4d. for the same light if supplied by the incandescence electric system.

"If we had to raise steam for generating the electricity, we should have extra expenses in coal and labour as follows:—Every ten lamps require one horse-power, so we should want 10 horse-power for our 100 lamps, which, with a fairly good boiler and engine, would consume 30lb. of coal per hour, or 40 tons per annum, which at 5s. a ton equals £10. In addition to this we cannot expect the engineer to do any turning, as he has to fire the boiler, and there are other small expenses to be met, bringing the extra cost through having to raise steam to £56 6s. 8d., giving a total for 100 lamps of £240 per annum, against £317 14s. 7d. for gas.

"I am sorry that the incorrect report as to the result of our adoption of the electric light has compelled me, in justice to yourself and Messrs. Crompton and Co., to enter in any way into the discussion going on between the advocates of gas and electric lighting, but I feel that after what has been said silence on my part would be misconstrued.—Yours, &c.,

(Signed) "J. H. Rogers.

"P.S.—I have purposely omitted the question of interest on capital in the case both of the electric light plant and gas plant, as they must necessarily vary in different works. I have, however, omitted to debit gas with any charge for repairs to pipes, burners, &c., which is considerable in any rooms where acid is used, and will fully make up for any advantage in interest in favour of gas."

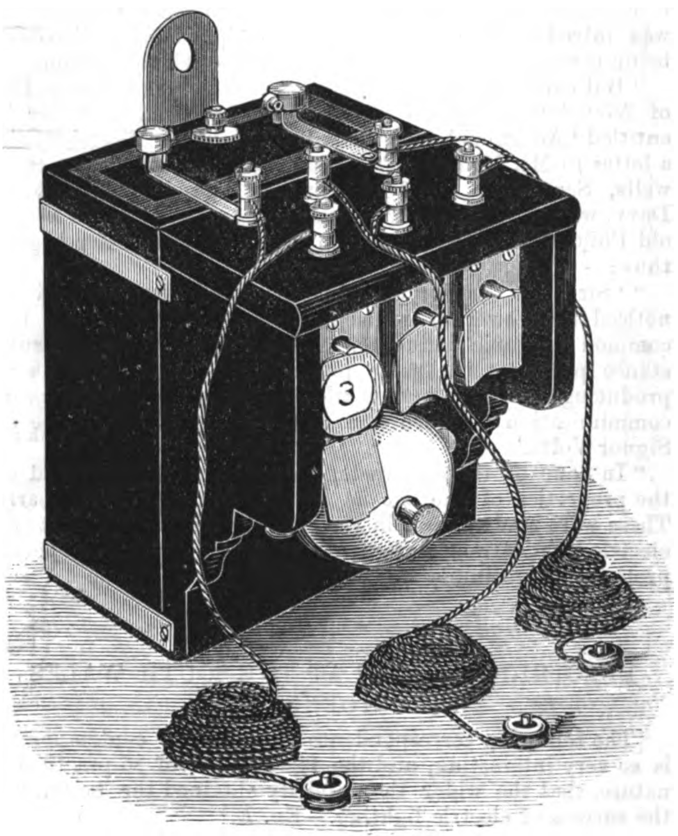
FISHERIES EXHIBITION.

The electric lighting at this exhibition is at length fairly complete, and we suppose will in future be seen at work. As is our custom we shall illustrate the machinery used so far as it has not been noticed by us before, and hence do not attempt to give a complete account of the work at present. It may not be out of place here to comment upon a stupid letter which appeared in the *Gl be.* The author of the letter tries to get up a scare because of non-duplication of plant, and hints that the breaking of a belt will lead to serious accidents. There is but one variation for the name of writers of this sort, they are either knaves or fools, and it is high time evenhanded justice was meted out to them. Unfortunately the damage effected by such writers cannot be repaired, inasmuch as neither technical journals nor common sense can reach the people who accept as containing some truth the statements of the writers. We agree with Mr. Proctor, that the scientific wisdom of the writers to our daily press is deplorable. Any rubbish is put into the papers, frequently corrections are not inserted. We will ask a series of questions in answer to the letter referred to. Is there one, or more than one steam engine, driving only one, or more than one dynamo? If there are—as there are—more engines and more dynamos than one, then more than one strap must break before *all* the lights are put out. The breaking of one strap might affect one circuit, but it would not affect all. We might to better purpose try to get up a scare because only one locomotive, as a rule, is put to one train.

To our subject, however, for we cannot take the trouble to call attention to every ridiculous flight of fancy perpetrated through the columns of the daily press. The portion of exhibition lighted is seven acres in extent. Over 25 miles of wire have been used, 56 dynamos generate the electricity, the apparatus being lent and exhibited by 15 firms. Messrs. Davey and Paxman supply the engine power. They were asked for 1,000 h.-p., but it is found that this was insufficient, and the engines will be driven hard to indicate 1,300 or more h.-p., so that some 4,000 incandescent lamps and 280 arc lamps may be used. Woodhouse and Rawson illuminate the vestibule with 350 of their lamps, supplied by an Elphinstone-Vincent machine. Siemens and Co. have arranged over 1,000 Swan lamps, supplying the current from two alternating Siemens machines—and have so arranged the circuits that alternate arches only are lighted from the same machine, so that should a strap break only one half, and these alternate lamps, would go out. Besides the Swan incandescent, Messrs. Siemens use four of their own arc lamps. The Jablochkoff Company lights several courts, as do Brockie lamps from a Gramme machine, while others are lighted by Lea lamps, also getting current from Gramme machines. The Gülcher Company has some 600 Crookes incandescent lamps supplied by Gülcher machines. Mr. Lever is lighting the dining room with twenty-eight of his arc lamps. It will thus be seen that we have here not only a grand display of apparatus connected with fishing, but one of the finest electrical displays yet made. Mr. Gooch, assisted by Mr. Henry, has in charge the electrical engineering of the exhibition.

COMBINED BATTERY BELL AND ANNUNCIATOR.

The annexed figure represents an exceedingly compact arrangement, in which a single cell is combined with an electric bell and annunciator in such a way that several



pushes and double wires may be attached to the bell and battery, and the annunciator will indicate from which push the bell is being rung. The arrangement is an improvement on the combined battery and bell brought out by the British Insulite Company, which we illustrated in a recent number. In that arrangement, although any number of wires could be attached to the combination, there was nothing to indicate which was the active wire. In the present improved design by the same makers there is added three drop shutters, exactly similar to those used in the Edison telephone switch-board. On this annunciator board is fastened a single insulite sealed cell, and below the drop shutters an electric bell, in which the hammer and magnets are all included under the bell dome. On the top of the board are three pairs of terminals, to which three double wires are attached, ending in the usual push. The arrangement is especially intended for offices and

Digitized by Google

domestic work. Any one can fit it up. The battery cell has a very low resistance, and as the electromotive force acting on the total circuit is small, both the bell and the annunciator magnets have to be wound specially for the purpose. This electrical part of the arrangement was constructed by the Telephone Construction and Maintenance Company, and the advantage of employing their form of drop shutter is that, even supposing the shutter to have fallen, it is possible to see by the chattering of the drop catch which push is signalling.

PRACTICAL TELEPHONY.

(CONTINUED FROM PAGE 137.)

The switch bell referred to on page 137, so connected up that the ringing key will act whether the telephone is hung up or not, is shown by Fig. 26. The path of the current in ringing up is as

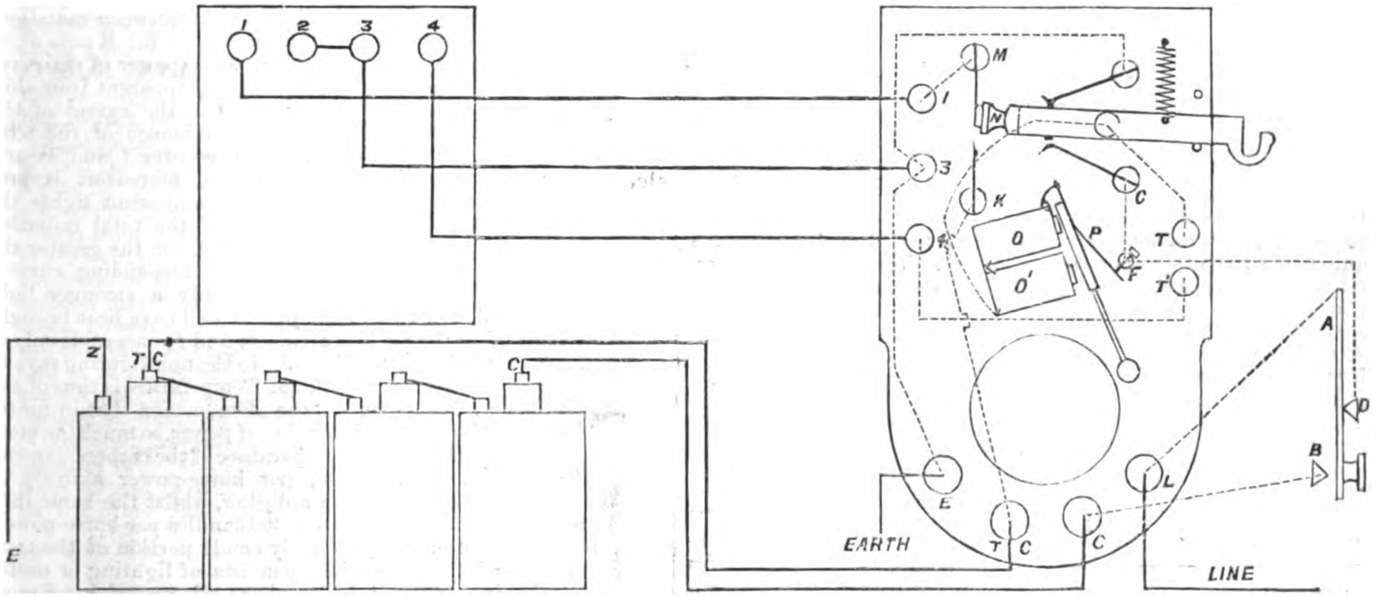


FIG. 26.

follows:—Battery carbon, terminal C, contact point B, spring A, terminal L, to line.

The passage of the arriving current is as follows:—Terminal L, spring A, contact D, bell contact point F, spring P, coils O O_1, switch hook lever, upper contact spring, to E.

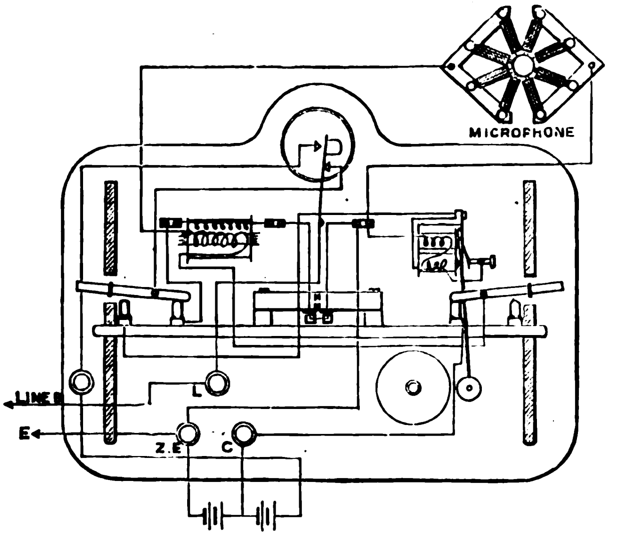

FIG. 27.

When the telephone is being used the path is the same as far as the bell contact point F, whence it goes to spring C, which is now in contact with the switch hook; thence to terminal T, through telephone, other terminal T, terminal 4 to transmitter, returning by terminal 3, and to earth.

A bell of this description, having two ringing keys as mentioned on page 137, was illustrated in *The Electrician*, No. 13. Vol. X., p. 299.

GOWER BELL INSTRUMENT.—This is the form adopted or use by the Post Office. The diagram of connections for these instruments without a relay is shown by Fig. 27 and with a relay by Fig. 28. The transmitter is a microphone of the radial type, and the receiver consists of a powerful magnet, both poles being utilised, two ear tubes, similar to speaking tubes, being fitted close to the diaphragm. The speaking is certainly loud, but somewhat lacks distinctness, and the tubes cause a sound similar to that heard in a shell when held to the ear.

JOHNSON TRANSMITTER.—This instrument is also used in this country to a certain extent, the microphone being the novel part of the arrangement, and gives excellent results. It consists of three carbon blocks, B, B_1, and B_2, Fig. 29, having two carbon pencils, A A_1, freely suspended between them. A secondary coil is employed as usual, and is shown at D. The current (using the accepted terms to convey the idea more clearly) passes from the battery F through the primary of the coil D, and thence to the block B_1, where it is divided, one half passing by the pencil A and the block B_1, the other half by the pencil A_1 and the block B_2, after which the divided current reunites in the wire G, which is connected to the opposite pole of the battery. When the transmitter is in use, the risk of a break of circuit is reduced by exactly one half. If the pencil A, for example, should break contact, the whole of the current—instead of one half—would pass through A_1, and no effect would be noticed in the telephone. But it is still possible that both pencils may break con-

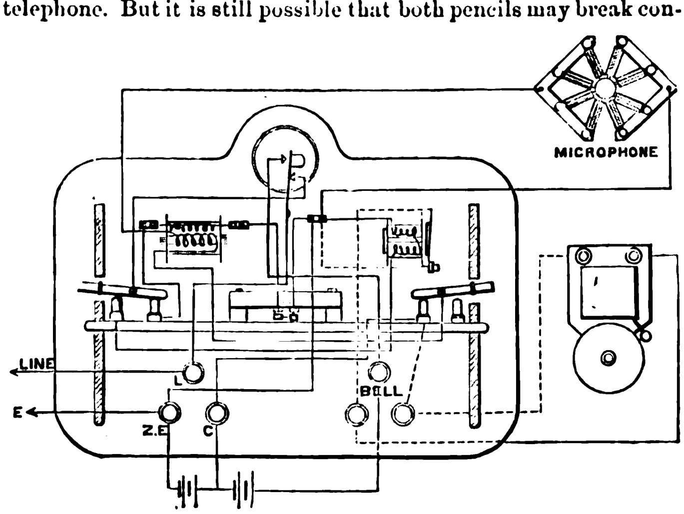

FIG. 28

tact together, and it is to avoid the result of this unanimity that the more ingenious part of the invention has been made. This consists of the shunt C, in which is inserted a resistance coil, C_1, the total resistance of the shunt being a little less than the total resistance of the microphone. The amount of current passing through the microphone and the shunt respectively is inversely proportionate to their respective resistances. It follows, therefore, that slightly more than one half passes through the shunt under ordinary circumstances, while the balance passes through the microphone. If now, in consequence of the impact of sound

Digitized by Google

waves or from any other cause, the resistance of the microphone is varied, the proportion of current passing through the shunt will be varied also. Thus, if the resistance of the microphone is reduced, the amount of current passing through the shunt is decreased. If, on the other hand, the resistance of the microphone is temporarily increased, or if its conductivity is broken, then the amount of the current passing through the shunt is increased, or the whole of the current is diverted through it. It will follow from this arrangement that the undulations of the line current are very considerably modified, and that the extreme variations are altogether eliminated, the result being more distinct articulation in the telephone, and freedom from the defects of buzzing, humming, or rattling noises. The ordinary Bell telephone is used as a receiver.

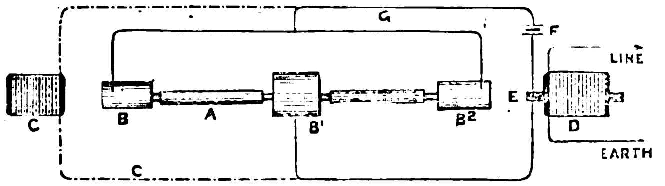

Fig. 29.

Adjusting Bells.—It will be necessary to see that all connections (see Fig. 25, p. 136) are tight, screw-post P, and screw *b* firm, and not shaking about, hold the hammer head D against the bell C, then adjust the screw *b* so that it all but touches the platinum point on spring *a*. See also that the armature *c* is quite clear from touching the poles d d_1. When the hammer is released the spring should draw the armature back, and the platinum point should make firm contact with the screw *b*. It sometimes happens that a bell rings badly from the spring not setting the armature back strongly enough. In order to know if this is the case, press with a wire the armature away from the poles lightly whilst the bell is ringing. If the ringing improves the spring and armature must be taken off, and the spring set out a little close to the fixed end. If the ringing improves when the wire is pressing the amature against the poles, the spring is too strong, and must be set in a little.

(TO BE CONTINUED.)

ON INCANDESCENT LIGHTING.*

BY WILLIAM SIEMENS.

(CONCLUDED FROM PAGE 119.)

There exists absolutely no difficulty in improving this system still further in the direction of higher illuminating power should a practical necessity arise for it. The firm of Siemens Brothers and Co. in Charlottenburg, for instance, who set a particular value in possessing in their incandescent lighting system lamps of most varied illuminating power, requiring similar E.M.F. and colour, makes, for example, 100 volt lamps of 130 candle-power. A short time ago a part of the Kochstrasse was experimentally lighted with such lamps, and the result was that the light about corresponded to that of the improved gas lighting in the Leipziger and Friedrichstrasse.

It is apparent from the table given above that the sectional areas of the carbons increase in quicker ratio than the illuminating powers and surfaces, and, as an increase of the durability is connected therewith, it follows that in an incandescent light system with lamps of different luminosity the weaker claim attention in a higher degree than the stronger, and it is therefore to be recommended as much as possible to give the preference to strong lights. As the E.M.F. at which the whole system is adjusted is chosen with regard to the least luminous lamp, so by leaving out these we can use higher candle-powers, and thereby attain a whiter light and greater economy.

It follows further that the advantage of the lamps of low E.M.F., which consists in the larger diameter and the greater durability, disappears still more, compared with lamps of higher E.M.F., the greater one makes their illuminating power. Thus, for example, the diameter of the Swan lamp carbon is 0·25mm., whilst the diameter of the 25 candle lamp of Siemens and Halske amounts to 0·27mm. This is particularly of importance when considering the lighting of large rooms.

The explanations previously given were made upon the assumption of identical temperature, materials, and substance. I will now enter into further particulars respecting these matters. For a certain work performed by the current E C there corresponds a fixed radiation. This radiation may be of very different kinds. Its character consists in an undulating movement of the æther, and the quality of a ray is determined by the length of its undulation or vibration, whilst its intensity depends upon the greatness of the amplitude. According to the extent of the undulation, dark lighting and chemical heat rays are distinguished. The maximum of the heating power lies in the dark rays. The quality of a ray only depends upon the temperature. The temperature has a two-fold influence on the character of the ray. Firstly, the intensity of each single ray is increased, and secondly, with higher temperature we obtain new rays of shorter length and of greater refrangibility. A white glowing body contains more red rays than when it is in a red glowing condition. According to Draper, all bodies begin at the same temperature (525deg.) to give forth the first lighting rays.

If a solid body is heated to a certain temperature, it will give forth a mixture of the most varied rays, from the longest waves to the shortest, which correspond to this temperature. The extent of this radiation will depend, however, upon the extent of the amplitude of the single rays, and this again is connected with the power of emission of the surface of the radiating body. According to Dulong and Petit there exists between radiation, temperature, and power of emission the relation : $R = m\,d^t$, in which R represents the total radiation, m the power of emission, and d a constant. The more important part, apparent from this, which t plays as regards m in reference to the extent of the radiation, is determined by the twofold influence of the temperature, as already mentioned. The greater t and m are, the greater is the total radiation, which, moreover, is proportional to the radiating surface. For incandescent lights the values t and m, in so far as the extent of the total radiation depends on them, are not of real importance, for the greater the total radiation the greater will be the corresponding current power (E C). By this means, therefore, only a stronger light would be produced, and this might just as well have been brought about by increasing the surface area. m and t concern us only in so far as the proportion of the lighting to the non-lighting rays in the total radiation changes with them. Temperature is thus of the greatest influence. This explains the phenomenon that in incandescent lamps, with a certain absorption of power, so much the more light is obtained the higher the temperature of the carbon filament. Thus one obtains, for instance, per horse-power scarcely 70 candles when the filament has a red glow, whilst the same in a white glowing condition gives over 300 candles per horse-power. It is, however, but a comparatively small portion of the total radiation in this latter case which consists of lighting or useful rays, and the incandescent lamps share this wastefulness more or less with all other artificial sources of light. Tyndall has given some data on this point. In his experiments he used a solution of iodine in sulphuretted carbon, which has the property of absorbing the lighting rays, but lets through the dark ones. From the proportion between the total radiation and the portion let through is estimated the proportion of lighting rays. This proportion amounts, for instance, in the case of an oil flame to 3 per cent. of the total radiation, in that of a gas-flame to 4 per cent., in a glowing white (heated) platinum spiral to 4·6 per cent., in an electric arc light to from 10 to 11 per cent. Thus, for this favourable light the useless portion of the radiation amounts to 90 per cent., and 90 per cent. of the work performed by the current E C is spent in the production of dark heat-rays. The economy of the carbon incandescent lights will be found between that of platinum and that of the arc light.

A question of interest is whether, assuming identical temperature for radiations of different substances, the proportion of the dark to the bright heat rays is a different one. This question as yet has been but little studied. If one heats in a furnace a piece of glass and a piece of iron to the same degree, on being taken out the iron will radiate a bright light, whilst the glass scarcely gives any perceptible light, though the temperature of both is the same. As the glass, however, on account of its great capacity for absorbing dark heat rays in the exchange relation between absorption and emission, is inclined to the radiation of dark rays, one can readily suppose that the difference in the radiation of light between iron and glass lies not merely in the differences of the total power of emission, but also in this, that glass, contrary to iron at the same temperature, sends out dark rather than bright rays. Exact experiments on this point are difficult.

Observations with a Maxim lamp showed, first, that a certain illuminating power corresponds to a fixed amount of work (E C). After a time, however, the illuminating power decreases without decrease in the resistance of the carbon, and, consequently, without E . C changing, the total radiation, however, in unit of time remaining constant. One might explain the fact by supposing the influence of the current to change the molecular character of the surface, and that this transformation resulted in an increased capacity of emission. A falling of temperature (as $R = m\,d^t$) would result, and consequently a

* Translated from the *Electrotechnische Zeitschrift*, March, 1883.

Digitized by Google

diminution of illuminating power. At the same time, one would suppose that by the proportional strengthening the current, or by the application of more work, the earlier temperature and luminosity of the filament could be re-established. Such, however, is not the case, for the increase of the illuminating power necessitates a disproportionately strong augmentation of power expended. Therefore, the carbon is at first more economical for the production of light than in the second state.

It is very difficult to determine the influence of surface change, having no means of bringing carbons to exactly the same temperature.

The importance of temperature is universally known. How high this temperature should be can only be shown by experience. I have mentioned that, assuming the lamp to last a certain time, the temperature of carbons of large diameter can be higher than those with small diameter. Corresponding to the difference of the temperature, the economy of the different systems of lamps varies, and from 100 to 200 candles are obtained per h.-p. I am thoroughly convinced that the incandescent light is susceptible of improvement, and certainly important advances are to be expected in the employment of carbons which can stand a higher temperature. It appears to me very inconsistent to expect the incandescent light to prove a formidable rival to the arc light. The field of action for the incandescent light lies, in fact, only where the arc light cannot be used.

That lamp is not the best with which, by the application of a certain amount of work, we can momentarily produce the most light; but the preference will be given to that which—assuming a fixed duration—is capable of bearing the highest temperature.

It is sometimes also thought that the size and form of carbon is a criterion of the economy of a lamp. Some maintain that the thickness of the carbon is desirable; others, again, are of the opinion that it cannot be too thin, and so on. All these assumptions, however, are erroneous. As I have already made prominent, the sole questions are those of temperature and surface, and it is a matter of perfect indifference how this surface is shaped, whether it belongs to a good or to a badly conducting carbon, or what the form of section.

Although specific resistance exercises no influence on the quantity of light obtained for the power E C (in which temperature and capacity of emission are taken as constant), yet, on the other hand, the proportion between C and E depends upon it. The work performed on one lamp is $= C^2 w$ or $\frac{E^2}{w}$.

For, constant illuminating power, diameter, length, and temperature is

$$C^2 w_s = \frac{E^2}{w_s} = \text{const.}$$

The connection between C E and w_s (the specific resistance) is expressed hereby.

On the ground of economy in the conductor a higher specific resistance will thus be advantageous, though the advantage is not great, as E increases in a far smaller degree than w_s.

A carbon with rectangular section has a larger surface than the same length with same sectional area of a circular carbon, and at the same temperature the radiation from the larger surface will surpass that from the smaller surface. To obtain the same surface the circular carbon must be lengthened. Then luminosity and durability are equal in both cases, as is E C, but R in the round carbon is greater than in the rectangular, because of greater length, thus making E greater in one case and C in the other.

The round form is to be preferred, as for the same work and durability we obtain greater economy by using a higher E.M.F.

The form of the Edison lamp cannot, therefore, be considered a suitable one. The sectional area of the 16 candle-power lamp is a rectangle whose sides are about 0·1· and 0·2mm. long. A circular-shaped filament with the same surfaces might be about $\frac{1}{5}$ to $\frac{1}{4}$ longer, using a correspondingly higher E.M.F. The same holds good in a yet higher degree of Cruto's hollow carbon shown at the Munich Exhibition. We may say, then, that form of sectional area is the best which gives the smallest circumference for a given sectional area. And this is the round form. For conductors this rule must be reversed.

I have now submitted the last of the points to which I desired to call your attention. It was not at all my intention to give you a complete survey over all the details of this extensive region, but my object was only to call some attention to matters of pressing importance which are of weight in judging the value of this kind of light. By what has been said the direction of progress and the method by which progress may be facilitated is indicated. Improve the carbons to bear a higher temperature, and give a surface favourable to the radiation of lighting or useful rays. Further, advances must also be made in the attainment of a high vacuum.

In conclusion, I would mention that endeavours are being made to diminish the cost of the conductors, which even for lamps requiring high E.M.F. is considerable. It is considered that about three amperes will be carried properly by one square mm. sectional area of copper, which is sufficient for three of the stronger lamps taking 100 volts of E.M.F. Currents of high E.M.F. can by means of a suitable apparatus be transformed into currents of lower E.M.F. at the place of consumption. Let us imagine, for example, a Gramme ring without any of the external magnets, covered with thin wire, through which the current is sent. With motion the magnetism of the ring rotates. Now, if on the ring there is a second coil of thick wire in this there will be a continuous current of lower E.M.F., which may be collected from a commutator rotating together with the first, but in such a way that the connecting lines of the two pairs of brushes stand perpendicular to each other. Thirdly, by the application of a kind of induction apparatus the currents can be automatically changed in direction. In this case alternating currents are sent through the conductors.

I content myself here with mentioning these different methods, the improvement of which may be of importance for incandescent lighting.

THE FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED).

The second ordinary general meeting of the shareholders of the abovenamed company was held at the Cannon-street Hotel last Tuesday, under the presidency of M. Philippart. The secretary (Mr. Herbert Canning) having read the notice convening the meeting, the report and accounts were taken as read.

M. PHILIPPART then addressed the meeting, his remarks being interpreted by the solicitor (Mr. J. T. Campbell). Referring to his arrest, M. Philippart stated that he had been accused out of spite in connection with old questions pending with the Belgian Government as to certain railway matters. Persons engaged in business similar to that of the Company, but with other systems, would endeavour to profit by his arrest, but by great precaution and efforts he had been able to maintain the situation as it was. All the agreements which he was entering into and about to enter into with the Government and other persons in France still remained to be carried out by him as soon as the question connected with his arrest was settled in Belgium, which he believed would take place within fifteen days, and he believed it would terminate in in the way most favourable to himself. As conveying an intimation of what he had been doing while under arrest the following extract from *L'Evénement*, of June 26, was read:—"The Electrical Tramcar—We were present to-day at a most interesting event. At half-past three in the morning a tramcar belonging to the Omnibus Company left the Place des Nations (formerly the Place du Trône) loaded with forty passengers. The car passed over the rails of the exterior boulevards. In an hour and five minutes it arrived at the Place de l'Etoile, and five minutes later at Ranelagh (Passy). No horses, no steam, no compressed air, no noise. The few people who were about stopped apparently astonished at the sight of the car moving noiselessly along without horses. The electricity which was stored in Faure's accumulators placed under the seats of the car moved a shaft which transmitted the movement to the wheels by means of a chain Galle (endless chain). From Ranelagh the car and passengers returned to the place from whence they started, having performed a journey of thirty kilometres (more than twenty miles) over perhaps the most difficult route in Paris over more than half of which the gradients vary from 0·01 to 0·058 per metre. At the crossing of the Boulevard Rochechouart the gradient is not less than 4 centimetres per metre, and there the car was stopped and started again with ease. According to technical experts who were present this must have required at least 20 horse-power. The gradient of the Avenue Wagram, 400 metres in length, with an incline of 0·035 per metre, was accomplished at the rate of six kilometres per hour, to the amazement of all present. At the Place de l'Etoile, and after the car had crossed the points placed on a very sharp curve, the enthusiasm became general, for an ordinary tramcar, fully loaded, had gone 30 kilometres, at an average rate of 11 kilometres per hour, over a difficult route, in a bad state of repair, and with hastily constructed machinery, by the means of 2 tons of accumulators. Here, indeed, is what is likely to revolutionise the whole system of traction of omnibuses, tramcars, and even railways. It is stated that 20 tons of accumulators would suffice to transport a hundred passengers from Paris to Marseilles, at the rate of 100 kilometres an hour, without stopping. The interesting experiment was carefully watched by the engineers of the Orleans Company and the Chemins de fer de l'Etat. MM. Massillon and Clark, directors of the omnibus company, were there also, accompanied by their traffic managers, but, strangest of all to relate, this important experiment was conducted by Simon Philippart himself!—yes, Philippart *ipse*. The day after the judges at Brussels set him at liberty he lighted up the *salons* of the Liberal Association of Brussels, then he came to Paris and organised the experiments above mentioned. Last night he left for London. Decidedly the shareholder in the company 'La Force et la Lumière' who has been vindictively prosecuting him in Brussels would have done better to have let him work on."

A translation from an article in *La Ville de Paris* of the 25th inst. relating to the same experiment was also read.

Continuing, M. PHILIPPART said that experiments had been made in London, but never with such success. He then observed that there were now 600 tramcars in Paris, or what might be considered equivalent to that number. They all carried fifty passengers each; the cars were heavier than those in London. The cost of the *traction power* of each car in Paris came altogether to about sixty francs a day, whereas by adopting accumulators this cost would not exceed twenty francs per car per day. Accord-

Digitized by Google

ing to the accounts of the Company each tramcar earned a profit of about twelve francs a day. Each car required fourteen horses during the day.

Mr. TURNER questioned the utility of the remarks, and suggested that the meeting should proceed at once to business.

The CHAIRMAN expressed his readiness to act in accordance with the wishes of the meeting.

Mr. TURNER thought the shareholders should see whether there was any money to carry out the works. Judging from the accounts there appeared to be no money to carry them out.

The CHAIRMAN remarked that the Company had no longer anything to do in England, the shareholders having approved of the sale of the residue of the English patents to the Sellon Company, having a preponderating interest in the French company instead. That company's patents were to be worked in France, and as the income of the Faure Company was to come from the working of the French patents, he thought it necessary that the shareholders should be informed of what was being done in France.

The CHAIRMAN stated that the experiments that were now being made in Paris were for the purpose of proving to the French people the value of these accumulators. There was no difficulty whatever in their having sufficient capital to carry out the matter in Paris as soon as they had shown that the accumulators possessed the advantages claimed for them.

Mr. TURNER wished to know the meaning of the accounts having been signed by the chairman "with a reservation, the nature of which I shall explain at the general meeting."

The SOLICITOR, on behalf of the chairman, said that on one side of the accounts there was an item "amount paid on 25,427 shares forfeited, of which 18,000 have been re-issued, £50,854." There was also on each side of the account, viz., on the debit side in the capital account and on the credit side among sundry debtors, the sum of £50,854 "for calls due on forfeited shares." With regard to these forfeited shares, these were standing in M. Philippart's name, shares belonging to the Société La Force et la Lumière, on which more than £50,000 had been paid. M. Philippart was desirous of assisting the Faure Company, and he considered that by allowing those shares to be forfeited on which more than £50,000 in hard cash had been paid by him, it would be, as it were, replacing the £43,000 which had been expended for the English patents and for working expenses, and the proposal he made to the Faure Company was to allow his shares to be forfeited. This was agreed to, but M. Philippart made it a condition that, as he was giving up those shares, representing £50,000, he should not be asked to pay the remaining calls due on them. The *procès verbal* did not properly explain the agreement which was come to; M. Philippart said, "When I give up my shares to the Company, in order that £50,000 of its capital may disappear, it is understood that I shall not be called upon to pay any future calls on those shares."

Replying to Mr. Turner, the SOLICITOR added that M. Philippart considered that he had made a present to the Company of that £50,000.

The SECRETARY stated that the 18,000 re-issued shares were re-issued to the Société la Force et la Lumière as £5 paid, with a responsibility on them of another £5.

A SHAREHOLDER observed that in point of fact nothing had been paid on those shares.

The SECRETARY replied that there was no necessity for this at present. He reminded them that an agreement was entered into by which the Company had to pay La Société la Force et la Lumière £200,000, and that society had taken those 18,000 shares, £5 paid, equal to £90,000, instead of cash.

The SOLICITOR stated that the issue of these shares to the Société la Force et la Lumière was merely carrying out an agreement which the shareholders had approved.

Mr. TURNER observed that he had not understood that such an agreement had been ratified.

The SOLICITOR, replying to Mr. Turner, said that M. Philippart was the only creditor of the Société la Force et La Lumière, and the largest shareholder. The shares that had stood in that gentleman's name really belonged to the Société la Force et la Lumière, which now held three-fourths at least of the shares of the Faure Company.

The SECRETARY, also in reply to Mr. Turner, stated that the shares standing in M. Philippart's name were forfeited in January, and that then there were no more shares left in his name but the number necessary for his qualification.

The SOLICITOR stated that the Company had become interested in three-fourths of the whole of the profits of the French Company.

After a few remarks from Mr. STAPLES, the Chairman said that the whole of his fortune was embarked in the concern, and he had the greatest hopes of its success. By means of electricity he calculated that the cost of traction of the Paris cars might be reduced, and if they could only make arrangements with the Tramway Company to give them half the profits they saved they would have at least twenty francs on 600 cars a day in Paris. That was £500 a day, and that was only as regarded the City of Paris. He was very sanguine that he had solved this question. He considered that the experiment he had made was eminently satisfactory; carried out in the presence of official persons competent to judge. He proposed to go on with those experiments for the next fifteen days, and he believed that the tramcar owners would become so satisfied that there ought to be no difficulty in getting them to agree to give the electrical company a portion of the large amount they would save by the use of electricity. Traction on railways, he pointed out, was very much easier than on roads. With regard to lighting by electricity, also, he maintained that it could not be carried on to any extent or in any satisfactory way without the use of accumulators. All he had got to do was to go on with perseverance.

In reply to Mr. Turner,

The CHAIRMAN stated that supposing he were convicted, the position would be very difficult, as he did not see how the affair would go on in France without him, but that his conviction appeared to him most improbable, seeing that the charges against him were unjust; notwithstanding the gravity of the charges made against him, he had been unconditionally set at liberty upon the insignificant bail of £600.

Mr. STAPLES then suggested that the meeting should be adjourned without passing any resolution, and that until the next meeting was held there should be no further call made.

M. CADIOT, in reply to Mr. Campbell, stated that the £23,000 in the hands of the Company when the present Board took office had been used in connection with the Company's business, and in subscribing to shares in other French companies as arranged by the agreement approved by the shareholders. The full particulars explained, however, could be seen on reference to the accounts at the office.

Mr. TURNER stated that the old directors, before they went out of office, said that there were no funds out of which to pay a dividend. Directly they retired the call was made by the present directors, and a dividend was paid. Was that dividend paid out of the call?

The SOLICITOR, in reply, said that M. Philippart considered that the dividend was paid out of the money gained in connection with the shares he had forfeited.

Professor AYRTON, in answer to a question, said that no accumulator whatever that he had seen could compare electrically or commercially with the Faure-Sellon-Volckmar.

On the motion of Mr. STAPLES, the meeting was adjourned to the 15th October.

Mr. STAPLES made a few remarks expressing sympathy with M. Philippart on account of the trouble he had gone through, and hoping that he would get over his difficulty, and that he would see the Company, in which he was so largely interested, turn out a great success.

The proceedings then terminated.

NOTES.

The Magazines.—In this month's *Nineteenth Century* Viscount Bury deals with "House Lighting by Electricity."

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended 29th June, 1883, amounted to £2,458.

German Telegraphs.—Between the years 1878 and 1882 the number of cells at work in German telegraph offices was increased by about 20,000.

Competing Companies in America.—A Bill prohibiting the consolidation of competing telegraph companies passed the Pennsylvania House last week.

The Edison System in New York.—American papers say that Wallack's and the Madison Square Theatres in that city are to be lighted by the Edison system.

Direct Spanish Telegraph Company.—The estimated traffic receipts of this Spanish company for the month of June were £1,552, against £1,963 in the corresponding period of last year.

Cable Repaired.—The Western and Brazilian Telegraph Company notify the repair of their Maldouado Monte Video cable, thus restoring telegraphic communication throughout the whole of their system.

A New Telegraph Stamp.—A postage and inland revenue stamp of the value of 2s. 6d., available for postage, telegraph, and inland revenue purposes, is now being issued, and will shortly be obtainable from all postmasters, &c.

The Patents Bill.—According to the *Daily News* it was possible that the Patents Bill might be got through Grand Committee yesterday (Friday). Failing that, our contemporary regards it as certain that it will pass this stage on Monday.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 22nd June, 1883, were £1,793, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Legal.—An American contemporary states that the Consolidated Electric Light Company, controlling the patents of William E. Sawyer and Albon Man, has brought a suit against the Edison Electric Light Company and others for infringement of patents.

West India and Panama Telegraph Company.—The estimated traffic receipts of this company for the half month ended June 30 were £2,478, as compared with £2,586 in the corresponding period of 1882. The February receipts, estimated at £6,742, realised £6,809.

An Electric Railway in Chicago.—Amongst the novelties at the Chicago Railway Exhibition is an electric railway, which is said to be largely patronised by visitors. On one day over 12,000 passengers are said to have been carried over the route in eight hours, without a hitch.

Electric Carbon, Storage, &c., Company.—We are informed that Messrs. Henry Bennett and Co., 131, Hope-street, Glasgow, have been appointed sole agents for the above company in Glasgow and district, and will in future undertake all business transactions there.

The Telephone in Belgium.—It is stated by a contemporary that an important Belgian paper, *La Flandre Liberale*, has a special telephonic service of its own between Ghent and Brussels. The instruments used are those of Mr. Van Rysselberghe, of the Brussels Observatory.

Government Telegrams.—A return has been issued showing that £33,995 was expended on telegrams by the Government in official communications with foreign countries in the financial year ending the 31st of March, 1881, and £25,043 in the year ending the 31st of March, 1882.

Catalogue.—Messrs. Davey, Paxman, and Co., of Colchester, who are well known as builders of engines for driving electric light machinery, have just published a new catalogue which is worthy of perusal. It contains capital illustrations of their different makes, with explanatory letterpress and price lists.

Mathematical Physics.—The University College of Auckland, New Zealand, is in want of a Professor of Mathematics and Mathematical Physics, and offers a salary of £700 per annum for the appointment. Applications should be made to Mr. W. Kennaway, at 7, Westminster-chambers, S.W., before the 31st inst.

Cuba Submarine Telegraph Company.—The number of messages passing over the lines of the Cuba Submarine Telegraph Company during the month of June was 3,120, estimated to produce £2,700, against 3,023 messages, producing £2,951 in the corresponding month of last year. The traffic receipts for the month of March, estimated at £4,500, realised £4,609.

The Electric Light in Bygone Days.—A correspondent writes:—"I read in the *Illustrated London News* for September 5, 1855, page 307, that the 'electric light has proved a failure in Deal, and resort is to be again had to gas.' Some particulars of this attempt before the introduction of dynamos would be interesting. Can you or your readers give any?"

London Hospitals and the Telephone.—An attempt is being made to organise a special system of telephonic communication between the great London hospitals and the private residences of their staff. If this very praiseworthy endeavour be successfully carried out, it may be the means of alleviating much suffering, and possibly of preventing many a death.

The Pilsen System.—We understand that the Pilsen Joel and General Electric Light Company are about to exhibit an installation of eight Pilsen arc lamps at the Cork Exhibition. We are also informed that the same company has just despatched an installation of 14 Pilsen arc lamps to Stockholm, which are intended for the lighting of one of the principal portions of that city.

Reducing Battery Expenses.—According to a recent report by Herr Kolb, secretary to the German Telegraph Administration, the expenses incurred during the course of the official year, 1881-82, in maintaining the 127,166 cells employed by that administration, amounted to £12,350. The Government recouped £2,727 of this amount, however, by the sale of copper crystals, zinc, lead, &c.

The Late Sir Edward Sabine.—The funeral of General Sir Edward Sabine took place on Saturday last at noon, at Tewin, near Hertford, where the family vault is situated. The body was brought by rail from London to Welwyn, and from thence was conveyed in an open crescent hearse to Tewin Churchyard. There was a large body of mourners, amongst whom were several members of the Royal Society.

Liverpool Junior Conservative Club.—The principal rooms of this club, which was opened on Tuesday, June 26, by Earl Lathom, have been fitted throughout with electric lights. Compound gas and electric fittings have been supplied by Messrs. Bennett Brothers, and the electrical part of

Digitized by Google

the work has been carried out by the Liverpool Electric Supply Company, under the personal superintendence of Messrs. Holmes and Vaudrey, the company's engineers.

AN INCOMBUSTIBLE INSULATOR.—A patent has recently been taken out for an incombustible insulating material. The inventor combines paraffin and castor oil with india rubber, and then mixes the compound with oxychloride of zinc or lead. By combining the paraffin and oil with the rubber, he states that he is able to incorporate with them a greater proportion of the substances used for rendering them imflammable. The inventor's name is A. Parkes, and the number of the patent 5,388 for 1882.

SUN SPOTS AND TERRESTRIAL MAGNETISM.—A telegram to *The Times*, from its Philadelphia correspondent, dated July 2, says:—"Professor Brooks, of Redhouse Observatory, Phelps, New York, reports telescopic observation of an enormous group of spots now central on the sun's disc, visible to the naked eye, the diameter of the group being 50,000 miles. They exhibit violent cyclonic action, electrical storms and aurora accompanying the solar outbreak. A brilliant aurora was visible on the earth at the time of observation."

ANGLO-AMERICAN TELEGRAPH COMPANY.—At a meeting of the Board of Directors of the Anglo-American Telegraph Company, held on the 29th ult., it was resolved, after placing the quarterly sum of £37,500 to the renewal fund, to declare an interim dividend for the quarter ending 30th June, 1883, of 15s. per cent. on the ordinary stock, and 30s. per cent. on the preferred stock, both free of income-tax, payable on the 1st August to the stockholders registered on the books of the company on the 30th June, 1883.

THE EDISON SYSTEM IN LONDON.—On the occasion of the dinner given by the Speaker at his residence on Saturday evening last the riverside terrace was illuminated by Edison incandescent lamps. Seventy-eight 16-candle and three 100-candle lamps were employed, the current being furnished by the Edison plant in the House of Commons. The Prince and Princess of Wales, who were amongst the guests, expressed much approval of the lighting arrangements. The Adelaide Gallery, Strand (Messrs. Gatti's) is being wired for 325 Edison lamps.

MORE REDUCTIONS IN GAS BILLS.—The price of gas supplied by the Gas Light and Coke Company to the street lamps of the metropolis has recently been reduced to 2s. 10d. per 1,000 cubic feet; while common gas (16 candle illuminating power), supplied to private consumers, will be reduced to 3s. per 1,000 feet from 1st January next. Now, if there is one thing more certain than another, it is that the electric light has had nothing to do with this reduction, or rather that the gas journals will say so. Other folks may be of a different opinion, however.

ANOTHER NEW ACCUMULATOR.—Mr. James Shepherd, of 45, Via Stella, and 3, Piazza Scala, Milan, has resigned his position as general agent of the Italian Edison Company, and has taken out a patent for an accumulator, which he is now manufacturing on an extensive scale. We hope shortly to be able to furnish our readers with a description of this battery, with which, we are informed, good results have been obtained. Mr. Shepherd introduced both the Brush and Edison systems of electric lighting into Italy, and was the originator of the present Italian Edison Syndicate.

THE METAL TRADES EXHIBITION.—There are but few exhibits at the Agricultural Hall of a strictly electrical character, although many of the exhibits will be found interesting to electrical engineers. Messrs. Mather and Platt show a spherical engine with an Edison dynamo—at least we were informed at the private view that the engine was "on the road." Messrs. Felten and Guilleaume exhibit a fine assortment of wire and wire rope. The Leeds Forge Company have fitted up a marine boiler as a boudoir, and light the interior by means of incandescent lamps. The current for these lamps is supplied by a battery.

EASTERN TELEGRAPH COMPANY.—The directors are inviting subscriptions for £500,000 £4 per cent. Mortgage Debenture stock, issued under the authority of special resolutions of the company, according to which this stock constitutes a first charge on the undertaking and revenue of the company, and the total amount issuable is never to exceed one-third of the paid-up share capital of the company for the time being. The present issue is made for redemption of terminable debentures falling due in October next, and for payment for the Trieste-Corfu Telegraph cable and other important expenditures on capital account.

THE MAXIM LAMP IN AMERICA.—The *Electrical World* states that a contract between the Maxim Electric Light and Power Company, of Philadelphia, and the Lamp Committee of City Councils of Lancaster, Pa., has been signed. The Maxim Company agrees to have sixty lights in position and lighted by August 10th, and sixty additional lights by September 10th. The company filed a bond in the sum of 10,000dols. for the faithful performance of the contract. That number of lights costs the city 16,800 dols. per year. Our contemporary does not say whether the lights are to be employed in the streets, or a public building.

RUSSIAN FEMALE TELEGRAPHISTS.—An Odessa correspondent writes as follows:—"According to the semi-official *Journal de St. Petersbourg*, the question of the right of female telegraphists to the receipt of pensions has at last been favourably and definitely settled, thanks to the energetic efforts of Major-General Bezak, Director of the Department of Russian Telegraphs. The statute fixing these pensions has just been approved. The right of pension will be acquired after twenty years service. After twenty-five years the *télégraphistes* may retire on full pay. Marriage will entail no limitation of pension, but on the contrary the pension passes to the children."

A FRENCH SOCIETY OF ELECTRICIANS.—The articles of association of this society have been made public. The title will be "Société des Electriciens," and the head-quarters Paris. The objects of the society will be to form a centre for the collection of particulars as to the progress of electricity in all lands, to discuss electrical questions, to popularise and develop the applications of electricity by periodical publications, meetings, public experiments, &c.; to study industrial and economic questions, Government administration, and other matters affecting the distribution and employment of electricity, as well as the question of the extended use of natural forces. The members of the society will be divided into the following classes:—Honorary, subscribing, founders, and donors, the last three paying subscriptions in the shape of an annual sum, or a lump sum, as the case may be.

ELECTRIC LIGHTING AT WINCHESTER.—During the Royal Counties Agricultural Society's Show held this week, the New Guildhall was most efficiently illuminated by the Pilsen system. The interior of the large assembly room and the exterior of the hall, including the clock tower, at an elevation of 85ft., were the special parts illuminated. The success of the undertaking has induced the city authorities to authorise a plan and estimate to be prepared for lighting a certain area of the city by this system with the view of adopting it during the coming season. The ordinary Schuckert dynamo and

Digitized by Google

the improved Pilsen lamps were used on the occasion referred to, and worked well. The motive power was supplied by a portable engine made by Messrs. Wallis and Stevens, of Basingstoke, which ran very evenly. The work was undertaken and carried out by Mr. R. Bayley for the city authorities.

THE ST. GEORGE TELEPHONE.—On Tuesday last a series of experiments were made in the presence of a number of gentlemen interested in the matter, with the St. George telephone, so named after its inventor, Mr. St. George, at No. 18, Telegraph-street, E.C. In this telephone a thin diaphragm of mahogany veneer is used in place of the ordinary metal one. The transmitter was placed in the stores of the St. George Telephone Company, South Arcade, Finsbury-pavement, E.C., about a quarter of a mile away, and the line resistance is said to have been equal to twenty miles of wire. Singing, the notes of a violin, and speaking were heard with distinctness, despite the fact that the overhead wires in this quarter of the City are multitudinous, and some induction effects might reasonably have been expected. The St. George receiver was described in these columns some months ago, and we hope to be able to give a description of the transmitter shortly.

THE PROVISIONAL ORDERS BILL.—In the House of Commons on Wednesday night, on the order for the second reading of the Electric Lighting Provisional Orders (No. 5) Bill, Sir H. Vivian asked whether any provision had been made for the representation of the district authorities in regard to this Bill, and whether it was intended by the Board of Trade to refer it to a select or a hybrid committee.—Mr. J. Holms said the electric light undertakings were of a novel character, and these were the first Provisional Orders on the subject which had come before the House. It was proposed to refer them to a hybrid committee, so that they might be fully considered; but the Government was very much in the hands of the House, and it was open to any one to make any other suggestion.—Mr. Stanhope said that unless the Bills were opposed it would not be of much use referring them to a committee, as the points of detail would not be properly brought out except by opposition. The Bill was then read a second time.

ELECTRIC LIGHTING FOR HOTELS.—An installation of three Pilsen arc and 28 Gatehouse incandescent lamps has just been completed at the Inns of Court Hotel, High Holborn. Two of the arc lamps are used for lighting up the central reading and smoking court, and one for the Holborn entrance to the hotel. The Gatehouse incandescent lamps, of 20 candle-power each, are used for lighting up the dining room on the Holborn side of the hotel. The current is obtained from dynamo machines driven by steam power at the central station of the Pilsen, Joel, and General Electric Light Company (Limited), in Whetstone Park, Holborn. The temperature and atmosphere of the dining room is found to be much more agreeable with the new class of light than when gas was used. We believe that this is one of the few cases in which arc lighting has been successfully adopted for reading and writing rooms, the well-known steadiness of the Pilsen lamp rendering it possible. The Hotel Company are to be congratulated upon this accession to the comfort of their visitors.

INCANDESCENT LAMPS.—A novel method of making this class of lamps has recently been patented by Messrs. Boulton, Soward, and Probert. They take a glass vessel of globular shape, having two platinum electrodes inserted therein at a suitable distance apart, and either solid or tubular. A carbonaceous gas is then introduced into the glass vessel. The outer ends of the electrodes are connected to an electric generator of high tension, and sparks caused to pass through the gas inside the globe, between the electrodes. In consequence of this the gas is decomposed, and a deposit of carbon takes place upon one of the electrodes, "which deposit," to quote the patentees, "is gradually built up by means of a rapid succession or continuous flow of sparks, and a bridge of carbon is thus formed, so that the space separating the said metallic electrodes between which the spark passes is completely arched over." This bridge forms the filament, and after exhausting the globe of air, the lamp is ready for use. The number of the patent is 5,373 for 1882, and it has just been published.

FUNERAL OF THE LATE MR. SPOTTISWOODE.—At noon on Thursday the remains of the late President of the Royal Society were laid in Westminster Abbey, the Dean of Westminster having acceded to the very numerously and influentially signed memorial asking that this honour might be paid to the mortal remains of one who so well deserved it. Amongst the pall bearers were Sir William Siemens, representing the British Association; Sir William Armstrong, the Institution of Civil Engineers; Dr. Evans, the Royal Society; the Duke of Northumberland, the Royal Institution; Mr. Childers, Her Majesty's Government; Mr. Andrew Cockerell, the Prince of Wales, and representatives of the other scientific societies. Mr. Spottiswoode is buried in the north of Poet's Corner. He is not the first of his name who has been deemed worthy of such a resting place, as one of his ancestors, Archbishop Spottiswoode, appears to have been buried in the Abbey many years ago. It is needless to say that electrical science was numerously and worthily represented at the graveside.

THE DISCOVERY OF ELECTRO-MAGNETISM.—In *Les Mondes* for the 30th ult., Dr. Tommasi quotes a passage from an article in an Italian journal of the 3rd August, 1802 (the *Ristretto dei Foglietti Universali*, published at Trent), according to which a certain councillor, Jean Dominique Romagnosi, caused a compass needle to be deflected by means of the current from a Volta pile. This discovery is generally ascribed to Oerstedt who did not make it until seventeen years later than Councillor Romagnosi. Dr. Tommasi asks, therefore:—(1) Must we attribute the merit of having been the first to observe the deflection of the magnetic needle by the action of the voltaic current to Oersted or to Romagnosi? (2) Had Oersted any knowledge of Romagnosi's experiment when he published his discovery in electro-magnetism? (3) Are there other *savants* who may have had a hand in this discovery? He leaves the answers to these questions to the consideration of the electricians who will shortly be assembled at Vienna, in the hope that some information may be elicited at the meetings to be held during the exhibition.

CHEAP TELEGRAMS.—In the House of Commons, on Monday last, Mr. Alderman Lawrence asked the Chancellor of the Exchequer whether the House would have an opportunity of discussing the various schemes for the introduction of cheap telegrams before the order was finally made by the Post Office.—The Chancellor of the Exchequer said the question could be discussed on the Estimates.—Mr. Alderman Lawrence gave notice that on the occasion of the introduction of the scheme of sixpenny telegrams he would move that it was not expedient, in order to reduce the minimum price to sixpence, to increase the present tariff for twenty words and upwards, as would be the case under the proposed scheme. He would also move that it was not expedient to

Digitized by Google

charge for the number of words in the addresses either of the receivers or senders. He intended to move the following as an alternative scheme:—"That addresses be considered of the value of 2d., that eight words at ½d. each would be 4d., and that 2d. added to 4d. would be 6d." His proposition was this: Eight words, 6d.; twelve words, 8d.; sixteen words, 10d.; twenty words, 1s.; twenty-four words, 1s. 2d.; twenty-eight words, 1s. 4d.; and thirty words, 1s. 6d."

CHELSEA AND THE ELECTRIC LIGHTING ACT.—At a meeting of the Chelsea Vestry on Tuesday, a report was brought up by Mr. Charles Mossop, the chairman of the Electric Lighting Committee, from which it appeared that the Metropolitan Board of Works had presented a petition against the preamble of the provisional order for Chelsea granted by the Board of Trade to the Metropolitan Brush Company, which had been approved of by the vestry. He pointed out that the vestry was the local authority named in the Act, and that the main sewers and works vested in the Metropolitan Board were already amply protected by the order, and in other respects that the Board had no direct interest in the parish, and protested against the interference with the principles of local self-government at the eleventh hour, more especially as the vestry had so fully mastered the subject and agreed with the board of Trade. He further complained of the want of courtesy of the board in presenting a petition without communicating with the vestry, and apparently obstructing the operations of the Act in the metropolis. The vestry unanimously approved the report, and resolved to support the provisional order and to oppose the action of the Metropolitan Board of Works, and sealed a petition accordingly to the House of Commons. During the discussion it was much deplored that there should be a want of unanimity between the vestry and the board, and a possibility of the ratepayers being involved in a double and entirely unnecessary expense.

ELECTRIC EXHIBITION AT VIENNA.—THE THEATRE.—From Vienna we learn that the theatre, which is to occupy the whole of the south-east gallery of the exhibition building, is approaching completion. It is to be very handsomely decorated, and will be lighted throughout by the incandescent system of electric lighting. The latter work has been entrusted to Messrs. Ganz and Co., of Buda Pesth, and will be carried out by Messrs. Braun and Heider, of Vienna, their agents. Swan lamps of 20 c.-p. are to be used. Fifteen will light up the entrance hall and ticket offices, 90 will be employed in the *foyer*, 184 in the auditorium, 30 in the orchestra, 90 in the dressing rooms, and 1,260 on the stage. Many of these latter will only be used occasionally, to produce changes of colour in the light thrown on to the stage. The dynamo which will supply the current, and which has been specially constructed for the purpose, will be situate in the machine room, some 350 metres away, the current being carried to the theatre by an underground cable. Messrs. Piette and Krizik, the inventors of the Pilsen system of arc lighting, will light the theatre with their lamps, so as to alternate the arc with the incandescent system, and thus afford an opportunity of comparing the relative values of the two methods for this class of lighting. This firm intend to light the auditorium by from 3 to 5 arc lamps, the stage by 2, which will act as footlights, and 2 or 3 at either wing. The remaining portions of the theatre will, however, continue to be lighted by the incandescent lamps.

THE ROYAL SOCIETY OF EDINBURGH.—The fourteenth ordinary meeting of this society was held this week at the Royal Institution rooms; Mr. Robert Gray, vice-president, in the chair. Professor Crum Brown, for the Astronomer-Royal, Professor Piazzi Smyth, read a note on the little *b* group of lines in the solar spectrum. The paper set forth that a number of spectroscopists, founding upon the results of imperfect observation, had been asserting of late that in the sun's atmosphere all or the most ordinary elements were decomposed into simpler bodies, and that in terrestrial experiments they found an apparent coincidence between the lines of the spectra given by two such substances as iron and nickel. That line they held was not really due to either iron or nickel, but to the basic element, as they called it, which was common to both. Professor Smyth demurred from this view, and submitted that in one of the most celebrated instances which were assigned, more perfect spectroscopic power enabled them to show that these apparently coincident lines were not really so.—Professor C. G. Knott contributed a paper on superposed magnetism in iron and nickel, which was followed by notes on the maximum density of water and surface emissivity by Professor Tait.—A photograph of the arm of a boy which had been struck by lightning, forwarded by Mr. Milne Home, was submitted for inspection. Professor Tait called attention to a marking on or under the skin resembling the foliage of a young carrot or of a yew tree, and added that the matter was worth the consideration of anatomists and physiologists.

A GALLANT RESCUE.—We have received the following from a Valentia correspondent, and have pleasure in finding a place for it in our notes:—"At Valentia, Ireland, on the evening of the 26th June, a little boy, five or six years old, named Michael Cremin, son of the hotel proprietor, accidentally fell over the pierhead into the water. His brother, a little older than himself, raised an alarm, which was heard by some persons about 100 yards distant, amongst whom was Mr. Daniel Herbert, one of the staff of the Anglo-American Telegraph Company, who, after running to the scene of the accident, divested himself of coat and vest and plunged into the water in a rapid tidal way, brought the child up from the bottom, and swam ashore with him. The child was taken to his home, where he is progressing favourably. A similar gallant rescue occurred here about two years ago, when, whilst bathing off Beginnis Island, the eldest son of Mr. J. Graves, the superintendent of the Anglo-American Telegraph Company, was seized with the cramp and sank. A lad named James B. Smith, also one of the staff, seeing this from the shore, immediately swam out to where he last saw him, in a strong tide, and after searching under water for him found him, and being himself so much lighter than the other, seized the latter by the foot, and swimming with one hand, dragged him ashore, where, after some time, he succeeded (without other help being available) in restoring him to consciousness, and ultimately the two rowed home a mile or more in their punt. Such acts as these deserve to be recorded to the honour of the rescuers in a journal devoted to electrical and telegraphic science."

ELECTRIC LIGHTING OF THE LAW COURTS.—Messrs. R. E. Crompton and Co., engineers to the Swan United Electric Light Company, have now completed the whole of the arrangements for lighting these courts by electric lights. On the evening of Friday, the 29th ult., Mr. Shaw Lefevre, M.P., First Commissioner of Works, made a formal inspection of the lighting arrangements, and was shown over the courts by Mr. R. E. Crompton and Mr. Swan. Mr. W. H. Preece, F.R.S., and a large number of ladies and gentlemen were also present. The large hall, as we have before stated, is lighted

Digitized by Google

by six Crompton arc lamps. There are 20 courts, each of which has from 20 to 24 Swan lamps, besides corridors, &c., which are lighted by the same means. To supply the necessary current six Crompton-Bürgin dynamos are placed in a temporary iron building outside the courts, and are driven by one of Marshall's engines. As these are not quite sufficient to feed the total number of lamps, however, 82 2 horse-power Faure-Sellon-Volckmar accumulators, made by the Electrical Power Storage Company, have been provided in the vaults under the courts. These are charged by day, and will supply enough current to light the remainder of the lamps, as well as affording a reserve which can be utilised in case of any temporary breakdown in one or other of the courts. It will be remembered that some parts of the very extensive buildings comprising the new Law Courts were lighted on the occasion of the opening ceremony, early in December last. Since then the work has been pushed on with all speed, and the result is the completion of one of the largest undertakings of this character that has been attempted. Those of our readers who care for fuller details of the arrangement of the machinery, &c., will find a plan of the engine room in our issue of the 9th December last; illustrations of the interior of the great hall, and some of the courts, showing the position of the lamps, in our issue of the 16th December; and diagrams of the switch-boards and connections, in our issue of the 23rd December. It only remains for us to congratulate the Swan United Company, and their engineers, Messrs. R. E. Crompton and Co., on the successful issue of their labours.

The Supply of Electricity by Local Authorities.—A paper on this subject was read by Mr. Killingworth Hedges, of Westminster, at the annual meeting of the Association of Municipal and Sanitary Engineers, which took place this year on the 28th, 29th, and 30th of last month at Oxford. Mr. Hedges commenced by pointing out the probable disadvantages of letting the supply of electricity slip out of the hands of the local authorities and become the property of a company who, though prevented by the Electric Lighting Act from becoming actual monopolisers in the sense that the gas and water companies now are, would probably act in a way which would entail many disadvantages on the consumers. The author recommends local authorities to obtain power to act as undertakers, but at present only to partially exercise this power by acquiring a site for the generating station and erecting a suitable building, furnished with steam or hydraulic engines. From this station electric mains would be laid throughout the district to be lighted, and would be of such a size that they could be handed over for a time to any company whose system was to be experimented on. The disadvantage attending a change of system on this plan would be comparatively small, as the streets would not be interfered with, and, in the event of the supply being inefficient, the provisions of the Act could be rigorously enforced. The author gave some useful rules and tables for proportioning the sizes of the mains, and proceeded to show the necessity of having some efficient means of automatically reducing the supply of each house in the event of the current increasing to an extent which would be dangerous. The necessity of a constant supply was pointed out, for which purpose the economy of using storage batteries as reservoirs of electricity already made up for the uncertain duration of their component parts, which, if unburdened with patents, could be replaced at prices little above the cost of ordinary lead. The meter system of charging for the supply was shown to be hardly developed at present, and the plan of maintaining a constant current during stated intervals would probably be more suitable to the immediate wants of the consumer, especially if the undertakers were to lay two or more service mains, which could be either used singly or coupled up, at the option of the consumer, by a simple apparatus, which would be verified by a system somewhat similar to the bell punch used by the tramway companies to check the receipts. The paper was followed by a discussion, in which Mr. Blakesley, C.E., M.A., and several members of the association took part.

Sixpenny Telegrams.—The following Treasury minute with regard to the reduction of the minimum charge for Post Office telegrams, dated June 14, 1883, has been issued as a parliamentary paper:—"The Chancellor of the Exchequer states to the Board that since the adoption by the House of Commons, on the 29th of March last, of a resolution that the time had arrived for reducing the minimum price of telegrams to 6d. he had carefully considered how and when the wish expressed by the House of Commons could be carried out. He reminds my lords that in his financial statement he said, 'After the resolution of the 29th of March, I do not think it would be respectful on my part to put out of question the reduction in the minimum price of telegrams. As I promised, I have already commenced a careful inquiry into the estimates made by the Post Office as to the cost under several plans of the reduction to the minimum charge of 6d. I cannot, at this moment, anticipate the results of that inquiry; but I propose to set aside £170,000 out of my balance to enable me, if possible, to carry out the change in the course of the present year.' Mr. Childers has since been in frequent communication with the Postmaster-General on the subject, and has ascertained that, if directions be now given to provide the additional plant, &c., expected to be required for the introduction of any rate, with 6d. as a minimum, the reduction could be made on the 1st October, 1884. Mr. Fawcett has satisfied him that it would be necessary first to expend about £500,000 in new main lines of telegraph and other works, of which as much as £200,000 might be brought in course of payment in the present financial year. The Chancellor of the Exchequer has also discussed with the Postmaster-General the probable loss which may be expected from the adoption of one or another of the tariffs suggested by Mr. Fawcett, with the following results: 1. Free addresses to be abolished, and ½d. charged for each word, including the address; minimum charge 6d. Estimated loss of income in first year of adoption, £170,000. 2. Address of receiver to be free, but that of sender to be charged for; 6d. to be charged for the first five words and 2d. additional for each subsequent five words. Estimated loss of income in first year £270,000. 3. Scale as in 2, but both addresses to be free. The loss would be larger than in 2, and the preliminary expense would be increased from £500,000 to £625,000. It appears to the Chancellor of the Exchequer that Scheme 3 involves too heavy a charge on the public; and without prejudging the question whether Scheme 1 or Scheme 2 should be adopted (a decision on which question may well be postponed for further inquiry), he recommends that general authority be given to the Postmaster-General for the necessary preliminary expenses, expected to amount to £500,000. It will, however, of course be necessary to obtain specific Treasury authority for each work in the usual manner. Mr. Childers is further prepared for an expenditure of £200,000 in the current year; and he recommends that the Postmaster-General be instructed to prepare a supplementary estimate not exceeding this amount for early presentation to the House of Commons in the usual manner. My Lords concur, and desire that a copy of this minute be sent to the Postmaster-General for his information and guidance."

ELEMENTARY ELECTRICITY.—XIII.

(CONTINUED FROM PAGE 104.)

Electrical resistance, like all other physical quantities, must be measured in terms of a unit of its own kind. The unit generally adopted is called an ohm. It was originally determined by a committee appointed by the British Association for the Advancement of Science, and was based on certain theoretical principles, which will be explained under the head of Electro magnetism. For the present it is sufficient to know that the ohm is the resistance of a certain coil of wire, measured at a particular temperature. The electrical resistance of all metals increases as the temperature is raised, the increase in the case of pure metals being greater than in the case of alloys. The British Association committee constructed a number of standard "ohms," of different alloys, and marked upon them the temperatures at which they were correct, but, after the lapse of twenty years, it appeared that the resistances of these standards had somewhat changed, and they were not consistent with one another. In addition to this, it has been found that the original determination of the absolute unit was considerably in error, and the International Committee have recommended that the standard ohm should be the resistance of a column of pure mercury, one square millimetre in section, and of a length to be determined in accordance with the electro-magnetic principles above referred to. This length will be between 104 and 105 centimetres.

The specific resistances of conductors are most conveniently expressed in ohms per cubic centimetre. A table so constituted shows the resistance in ohms of a cube of the substance of one centimetre edge when the current flows from one face to the opposite face parallel to the edges of the cube.

Table of resistances in ohms per cubic centimetre.

Copper	·00000165
Silver	·00000165
Gold	·00000210
Aluminium	·00000215
Zinc	·00000569
Platinum	·00000916
Iron	·00000983
Tin	·00001336
Lead	·00001985
Antimony	·00003590
Mercury	·00009619
Bismuth	·00013265
German silver	·00002117

The resistance of conductors increases rapidly with the temperature. Most of the pure metals experience an increase of resistance of about ·3 per cent. for an increase in temperature of 1 deg. C., or about one part in 330. The resistance of mercury increases by only ·072 per cent. per degree centigrade, or one part in 1,390. The resistance of German silver increases by only ·044 per cent., or one part in 2,273, and that of platinum silver alloy by ·031 per cent., or one part in 3,226 for each degree centigrade. It is on account of their low temperature variation that these alloys have been selected as the materials for standard resistances; but it appears that their co-efficient of temperature variation depends very much upon their state of annealing, and is liable to change, as is also their resistance at any given temperature, by lapse of time, and thus an uncertainty is introduced when standard coils of these materials are employed. It is for this reason that it has been decided to aodpt a column of pure mercury as the standard ohm.

When the resistance of any substance is known in ohms per cubic centimetre (or per cubic inch) it is easy to calculate the resistance of a wire of any given length and section, since the resistance is proportional to the length, and inversely proportional to the sectional area of the conductor. For very rough purposes it is convenient to remember that the resistance of a mile of copper cable one square inch in section is a little more than $\frac{1}{25}$th of an ohm.

Resistance coils and coils of insulated wire are generally constructed of German silver or platinum silver alloy. The wire is first doubled (for a reason to be explained later on), and then wound upon a bobbin, the ends of the wire being connected to stout copper terminals. These coils are so adjusted as to represent any required multiple or submultiple of an ohm. They are usually arranged in resistance boxes, with a contrivance by which any coil can be immediately thrown into or out of circuit. The adjustment of these coils and the construction of resistance boxes will be described when we speak of electrical measurements. In the early resistance boxes constructed by Wheatstone the coils represented miles of telegraph wire, some single coils representing 50 miles of wire. The resistance corresponding to a one mile coil of Wheatstone's is about 12·7 ohms. The temperature at which they are "correct" should be marked on all resistance coils.

The methods of comparing the resistances of conductors will be described under electrical measurements. When the resistance of a given specimen of wire has been determined, its resistance per cubic centimetre may be found by calculation when its length and diameter are known. The length of the sample can be determined with sufficient accuracy by ordinary measuring instruments when the wire has been straightened. The diameter is best determined by weighing the sample in air and in water. The weight of water displaced gives the volume of the wire, and hence its sectional area can at once be found, its length being known. For example, the following results were obtained with a sample of hard phosphor bronze wire. The length of the wire was 617·25 centimetres. Its weight in air was 60·585 grammes, its weight in water 53·325 grammes. The weight of water displaced was therefore 7·26 grammes. At the temperature of the water one gramme measured about 1·001 cubic centimetres. Hence the volume of the wire was 7·267 cubic centimetres. Its sectional area was therefore $\frac{7{\cdot}267}{617{\cdot}25}$ square centimetres. Its resistance was ·379 ohm. Hence its resistance per cubic centimetre was

$$\frac{{\cdot}379 \times 7{\cdot}267}{617{\cdot}25 \times 617{\cdot}25} \text{ ohm, or } {\cdot}00000722 \text{ ohm,}$$

which is rather more than four times that of pure copper, the resistance of pure, hard-drawn copper being ·00000165 ohm per cubic centimetre.

The electromotive force between the extremities of a conductor is measured by the number of units of work done on a unit of electricity in passing from one end of the conductor to the other. It is, in fact, identical with the difference of potential between the ends. If we say that a current, C, is flowing in the conductor, we mean that C units of electricity pass across any section of the conductor in a second. Hence if an electromotive force, E, send a current, C, along the conductor, the work done in each second will be E C units.

Similarly, if E denote the electromotive force around a circuit, and C the current in the circuit, then E represents the number of units of work done upon the unit of electricity, as it goes completely round the circuit, and E C will represent the number of units of work done in a second.

The work done in driving the current round the circuit is derived from the battery, engine (and dynamo), or other source employed for the production of the current. Of this work some may be expended by the current in decomposing chemical compounds which may form a portion of the circuit (electrolysis), some may be employed in producing motion in magnets, or in other conductors, or in the conductor itself, as in the various forms of electric motors; some may be expended in producing currents in other conductors, as in the induction coil. But if no energy is expended in any such ways the E C units of work done by the electric forces during each second must be converted into heat within the conductor, and must be the mechanical equivalent of the heat so produced. This is the case in a metallic wire which is conveying a current, but is itself stationary, and not in the neighbourhood of any moving wires or magnets. Now, by Ohm's law, if R denote the resistance of the conductor, $E = C\,R$. Hence the amount of work converted into heat by the passage of a current C through a conductor (or con-

Digitized by Google

ducting circuit) of resistance R is C^2R, and increases as the square of the current.

This theoretical conclusion was verified experimentally by Dr. Joule, and is known as Joule's law. If H denote the amount of heat developed in the wire per second, expressed in mechanical units, then Joule's law is expressed by the equation,

$$H = C^2R.$$

Thus the heat generated in a conductor depends only on its resistance and on the strength of the current flowing through it, and increases as the square of the current.

The heat generated per second may also be expressed in terms of the electromotive force between the extremities of the conductor, or, if the conductor form a closed circuit, the electromotive force round the circuit, and the resistance, thus:

$$H = \frac{E^2}{R}.$$

Hence, we have:

$$H = E\,C = C^2R = \frac{E^2}{R}.$$

The practical units of current (the ampere), and electromotive force (the volt) are such that the work done per second when a current of 1 ampere is sustained by an electromotive force of 1 volt is 10,000,000 ergs. Now, one horse-power is equivalent to 550 foot-pounds, or, about 7,458,000,000 ergs per second. Hence, if an electromotive force of 1 volt be employed to send a current of 1 ampere round a circuit, work will be done at the rate of $\frac{1}{745.8}$, or nearly $\frac{1}{746}$ horse-power. This rate of doing work is called a watt.

The absolute units of current and electromotive force are so related that 1 erg per second is done by the unit electromotive force upon the unit of current. The volt is equal to 100,000,000, or 10^8 absolute units of electromotive force, and the ampere to ·1 absolute unit of current. Hence the work done by a volt upon an ampere in one second is 10,000,000 ergs. The ohm is 1,000,000,000, or 10^9 absolute units of resistance, and is such that a volt is capable of maintaining a current of an ampere through an ohm.

If an electromotive force, E, be employed to send a current, C, the horse-power exerted will be $\frac{1}{746}$ E C.

Similarly, if a current of C amperes is made to pass through a conductor whose resistance is R ohms, the horse-power required to sustain it will be $\frac{1}{746}$ C^2 R.

For example, if a 20-candle lamp requires an electromotive force of 110 volts between its terminals, and allows a current of ·6 ampere to pass, the horse-power actually required to light the lamp will be $\frac{110 \times {\cdot}6}{746} = {\cdot}0885$, nearly.

Again, suppose the current for 20,000 lamps, each requiring ·6 ampere, is transmitted along a cable having a resistance of ·1 ohm, the horse-power wasted in sending the current through the cable will be $\frac{12000^2 \times {\cdot}1}{746} = 19303$, nearly. Hence, conductors of very much less resistance must be employed in conveying the current for so large a number of lamps, and hence the lamps should be very near to the dynamos, or else conductors of very great sectional area must be employed.

When insulated copper cables, about an inch in diameter, are employed for the transmission of currents, it is found that if the current much exceeds 1,750 amperes per square inch of section of the conductor, the heat generated will cause a rise of temperature sufficient to injure the insulating material. Hence, on no account should the currents employed in electric lighting be allowed to exceed 1,750 amperes per square inch of section of such cables. If the diameter of the cables is greater the heat cannot escape at a rate proportional to the sectional area, and the amount of current per square inch of section of the conductors must be reduced. Hence, it is not generally advisable to use conductors of very great diameter, but when a current of several thousand amperes has to be transmitted it is best to use several cables in which the conductors are about an inch in diameter.

But in most installations considerations of economy will assign a limit to the amount of current transmitted per square inch of section of the conductor, which will be reached long before the maximum of 1,750 amperes per square inch is obtained. This limit depends upon the cost of power (price of coal, &c.) in the neighbourhood. For a given current the larger the conductor the less will be the power wasted in the transmission of the current, but the greater will be the interest (and depreciation) on the cost of the conductor. If the dimensions of the conductor be increased a point will presently be attained when any further increase in the diameter of the conductor will involve a greater expense in interest, &c., than will be saved by economy in power. This determines the most economical dimensions of the conductor. The limit will be attained when the interest on the whole cost of the conductor is equal to the annual cost of the energy wasted by the production of heat in the conductor. Suppose, for example, that a cable costs £10,000. We may suppose that its depreciation is very slight, and may take £500 as the annual cost of the cable. Suppose the current is flowing for 1,500 hours in the year, and the cost of power is $\frac{1}{3}$d. per horse-power per hour. Then 6s. 8d. per hour (during which it is in use) is the cost of the cable, and this is equal to that of 240 horse-power. Hence, if the energy wasted in cable exceed 240 horse-power, it will be economical to use a larger cable at an increased capital outlay, but if the energy wasted in producing heat in the cable is less than 240 horse-power, it would have been economical to have laid down a smaller cable. If a cable with a conductor of one square inch in section has a resistance of $\frac{1}{25}$ ohm per mile, and costs £1,500 per mile, this gives a limit of about 1,000 amperes per square inch of section as the most economical current, whatever be the length of the conductor.

If the ordinary type of Swan lamp be employed, requiring 1·2 ampere per lamp, it follows that one square inch of sectional area of the conducting mains will be required for every 833 lamps in circuit, or about 650 lamps might be advantageously served by a conductor 1in. in diameter. If lamps requiring only ·6 ampere are employed, 1,300 lamps should be attached to a conductor 1in. in diameter. If power can be supplied at a cheaper rate than $\frac{1}{3}$d. per horse-power per hour, or if conductors cost more than we have assumed, the strength of the current per square inch of the conductor should be increased.

LIGHTING THE PAVILION AT BRIGHTON.

We have recently examined the electric light arrangements carried out by Mr. Magnus Volk, to light the Pavilion at Brighton. Among the many difficulties which an electrical engineer has to contend against in an installation of this kind is that arising from the specification not to interfere with the existing gas burners. The results, therefore, although they may be very good, are really not the best, because the very best method cannot be adopted. To ensure the best effect the work must be commenced *de novo*, and hence we are inclined to appreciate more highly the success which is obtained under difficulties.

The Pavilion at Brighton has a history. In its most modern phase it is the centre of all the public amusements at Brighton. Here are held the balls, the *soirées*, the *conversaziones*, the musical *réunions*, and the thousand and one gay gatherings of a lively seaside resort.

Few public buildings are well ventilated, and the Pavilion at Brighton is no exception to the rule; hence the heat generated by the numerous gas jets, in addition to the vitiation of the air therefrom, was an objectionable feature of the crowded gatherings in these rooms. The corporation decided to try how far the use of electricity would improve these matters, and the work was entrusted to their electrical engineer, Mr. Volk.

The preliminary experiments were successful, but suggested various alterations in the distribution of the light in the permanent arrangements. These are being carried out, and no

Digitized by Google

doubt the installation will within a very short time be completed.

General Particulars.

The machinery consists of a 40 horse-power nominal Robey semi-fixed engine, fitted with Korting's injector, in addition to the feed pump. The ashpit is carried from under the firebox to a trap in the yard, so that the ashes can be removed without causing dust in the engine room. The power is all taken off one side of the engine by a 16in. belt, owing to the limited space at disposal. The engine makes a maximum of 82 revolutions per minute.

The current is generated by a Siemens alternate current dynamo for 500 Swan 20 candle-power lamps, arranged in multiple arc, with two in series, running at 600 revolutions per minute.

are inserted in every branch, and in some cases to every pair of lamps.

The lamps are disposed as follows:—

Room.	No. 20-candle Swan lamps.	Original No. gas burners.
Entrance hall	12	20
Corridor	46	74
Music room	104	216
North drawing room	40	40
Saloon	52	64
South drawing room	32	40

Total resistance of lamps 0·321 ohm.

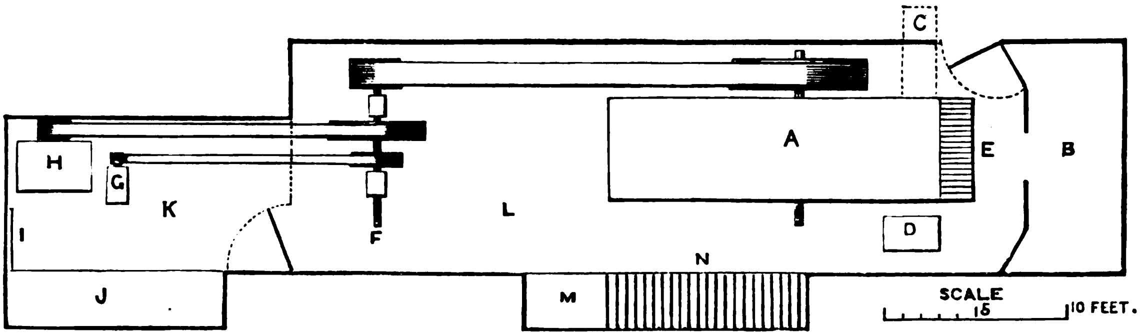

Fig. 1.—A, 40 h.-p. nominal semi-fixed Robey Engine. B, Coal Bunker. C, Sunk Ashpit, extending from under fire-box to trap in yard, for convenience in removing ashes. D, Sunk Water Tank. E, Grating, with Drain in bottom, to carry away water when "blowing off." F, Countershaft, &c. G, Exciting Dynamo, Siemens D^2. H, Alternating Current Dynamo, Siemens W O. I, Terminal Board. J, Bench. K, Dynamo Room. L, Engine Room. M, Cupboard. N, Air Grating.

The exciter used is a Siemens D_2. The former machine has an armature resistance = ·0137 ohm, with field magnets having a resistance of 3·8 ohms, the E.M.F. at the terminals being 94 volts. The field magnets are excited by a current of 25 amperes, the exciting machine having an armature resistance = ·3 ohm, and field magnets = 32 ohms.

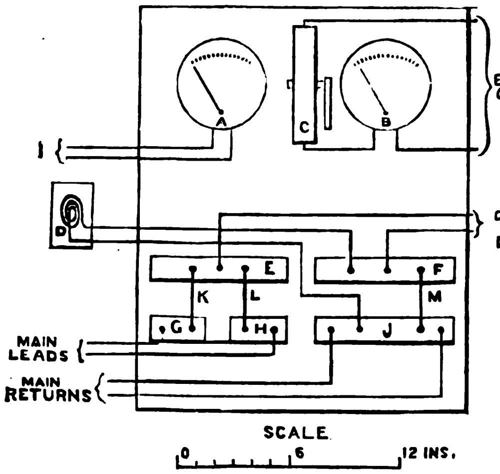

Fig. 2.—A, Volt Meter, the leads reaching to the point of distribution. B, Ampere Meter, for exciting current. C, Switch for exciting current. D, Siemens Dynamometer for main current. E, F, G, H, J, Terminal Plates. K, L, Lead Plugs. M, Short-circuit Plug for Dynamometer.

The main leads consist of four cables, each 280 yards long, two acting as one lead, each consisting of a stranded copper conductor, covered with two layers of gutta percha and a covering of tarred jute and tape. The approximate resistance of the main leads is ·044 ohm. The branch leads consist of a stranded copper conductor of 14 wires, each ·07 inch diameter, covered in the same manner as the main cables to a total thickness of 0·62 inch. The small branch leads on the chandeliers are covered with asbestos yarn, and fusible plugs

The rooms when lighted by gas required to have candles on the tables at banquets, and on the platform at concerts. The illumination is now so ample that candles are not required. The large number of lamps used in the banqueting room is owing to many having been added for decorative effect. The whole 500 lamps were originally put up, but were found to be in excess of the requirements. The reduced number also places the resistance of the leads to that of the lamps in a more favourable aspect, as owing to the comparatively short time the lamps are in use (about 500 hours per annum) it was not advisable to expend a greater sum on the main leads. The switches are arranged as follows:—Those for the music and drawing rooms are near their respective rooms, the centre and side chandeliers can be controlled separately, and raised or lowered by means of resistances. The switches for the rest of the building are in a case, with plate glass front, in the entrance hall.

The work has been one of considerable difficulty, owing to the peculiar decoration (Chinese) of the building, and the restrictions imposed by the authorities. The work has given the greatest satisfaction, and the estimate was only exceeded by five pounds.

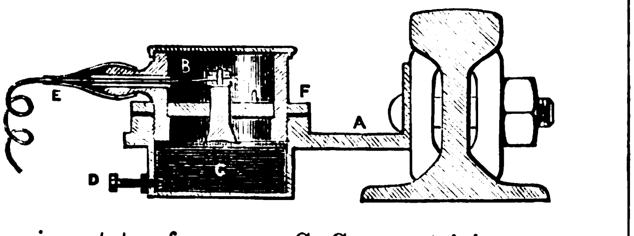
ELECTRICAL RAILWAY SIGNALLING.

We take the following from our Parisian contemporary, *L'Electricien*:—

"We know the difficulty of making a good electrical contact when it is to be worked by a train running at a high speed, and that this contact is exposed to all kinds of atmospheric changes with scarcely any attention. It is to meet the requirements of a contact of this kind that M. L. Mors has invented the contact represented below, of which the principle and disposition are easily understood by reference to the description which accompanies the figure. It consists in utilising the vibrations produced by the passage of the train upon the rail to which it is fixed, to produce, by the movement of the mercury, a contact in a hermetically-closed space, which continues during the passage of the train. The contact works any apparatus whatever—bell, signal, disc, &c. Experiments

Digitized by Google

made upon the Paris-Lyons-Mediterranean line have given satisfactory results. The apparatus may be applied in any case where it is required that a mechanical vibration shall cause automatically a corresponding signal. A. Lever, bent at the end to be riveted to the fish plate. B. Contact cone, insulated from the iron box by a piece of ebonite or wood, upon which is a small plug, which is removed to replenish the mercury in the cup, if necessary. The large surface of the cone is about 2mm. from the surface of the



mercury in a state of repose. C. Cup containing mercury. This cup communicates with the rail by the lever, and forms the "earth" pole (copper or zinc, according to position). D. Small screw for regulating height of mercury, also for emptying the cup. E. Nipple, through which is forced the junction cable, covered with a thick india-rubber tube; upon this tube is placed another tube, which covers the nipple in such a manner as to form a hermetically closed joint. F. Iron cup containing mercury."

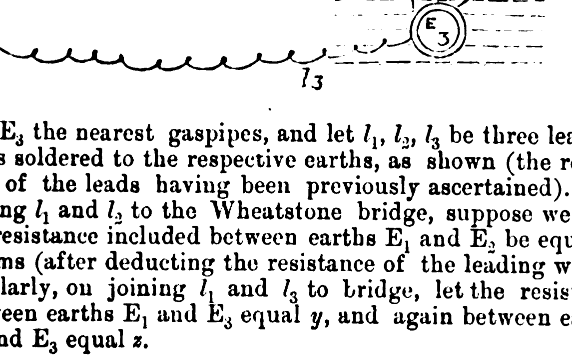
CORRESPONDENCE.

TESTING LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In answer to "T. L. P.," I am sorry that, being out of town, I have not got my test book with me, but, as near as I can remember, I shall give him the results of one of my tests, after explaining what is meant by "*Absolute* resistance in ohms to earth of the lightning conductor."

In the diagram below let L C be the lightning conductor attached to earth E_1, whose absolute resistance to earth has to be determined, while E_2 and E_3 are two other earths, say E_2, the suction pipe of a pump communicating with a well,



and E_3 the nearest gaspipes, and let l_1, l_2, l_3 be three leading wires soldered to the respective earths, as shown (the resistance of the leads having been previously ascertained). On joining l_1 and l_2 to the Wheatstone bridge, suppose we find the resistance included between earths E_1 and E_2 be equal to x ohms (after deducting the resistance of the leading wires). Similarly, on joining l_1 and l_3 to bridge, let the resistance between earths E_1 and E_3 equal y, and again between earths E_2 and E_3 equal z.

Then (1) $E_1 + E_2 = x \ldots \therefore$ (4) ... $E_2 = x - E_1$.
(2) $E_1 + E_3 = y \ldots \therefore$ (5) ... $E_3 = y - E_1$.
(3) $E_2 + E_3 = z$.

Now substitute the values E_2 and E_3, as found by equations (4) and (5) in equation (3),

and we have $$x - E_1 + y - E_1 = z,$$
$$\therefore x + y - z = 2\,E_1;$$

or the absolute resistance to earth of

$$E_1 = \frac{x + y - z}{2}.$$

For example, I got something like the following: $x = 1{\cdot}1^{\omega}$, $y = 2{\cdot}3^{\omega}$, $z = 1{\cdot}8^{\omega}$ testing from the points of the lightning conductor.

Substituting these values in last equation

$$E_1 = \frac{x + y - z}{2} = \frac{1\cdot1 + 2\cdot3 - 1\cdot8}{2} = \cdot8 \text{ ohm}.$$

Therefore, the absolute resistance to earth of the lightning conductor through its earth, E_1 is only 0·8 of an ohm, instead of 1·1 ohm, as indicated by the first test or the resistance simply included between earths E_1 and E_2.

In this way I tested for the resistance of the earths used at several well-known cable stations, as well as the earths used on board telegraph steamers, and of two lightning conductors I put up at Malta about four years ago.

It is a very necessary and important matter either in the fitting up of a telegraph station or in the testing of a cable, to see that you have as perfect a low resistance an "earth" as possible. I well remember a case in the Levant, when, to all outward appearances, there was a good earth at an outlandish cable hut situated some little distance from the shore on dry ground which I used while localising a fault. Finding that my results threw the apparent position of the fault right away into the interior of the island opposite where the other end of the cable was landed, I had the apparently sound earth tested, and got over 50 ohms R. Upon unearthing the end of the cable for some distance, I found that a piece of newer cable had been added on to the original shore end to bring it up to the cable hut, and as the splice lay in dry, sandy ground, with little or no metallic contact between the sheathings, the true cause of the earth resistance was unearthed, and the splice properly made, when the earth gave less than one ohm, and the fault correctly localised.

In the case of lightning conductors, I think they should not be passed unless their absolute resistance to earth, including everything from the points downward, give under two ohms resistance in the dryest season. "J. L. P." has evidently got an excellent earth connection to his lightning conductor. The Government and municipalities should insist upon all public and prominent private buildings being tested periodically by some competent and trustworthy person.—Yours, &c., A. J.

Arran, June 26, 1883.

AN ARC LIGHT REGISTER.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: The following simple device for automatically registering how an arc lamp has been burning during an evening having proved of such practical use at the Brighton Electric Lighting Station during the last six months, I think an account of it will interest some of your readers:—

The apparatus consists of three parts. A clock for rotating a piece of sensitised paper, a lens for throwing an image of the arc on this paper, and a screen to shut off all the direct light from the lamp, except that which passes through an angular opening.

Fig. 1 shows the apparatus complete. A is an ordinary American twenty-four hour clock, whose minute hand axis has been prolonged for about 2in. On this axis is fixed a light 12in. zinc disc, D; this carries the sensitised paper, which is held flat to it by a centre boss, B, with twelve equidistant radii made of thin brass wire, one being thicker than the rest to indicate the hour.

C is a triangular piece of zinc 10in. high and 3in. wide at

Digitized by Google

the base. This carries a small 5in. focus lens behind an oblong aperture, N, ½in. wide, and a ¼in. in height.

F is a screen made of zinc, about 10in. square. H L is an

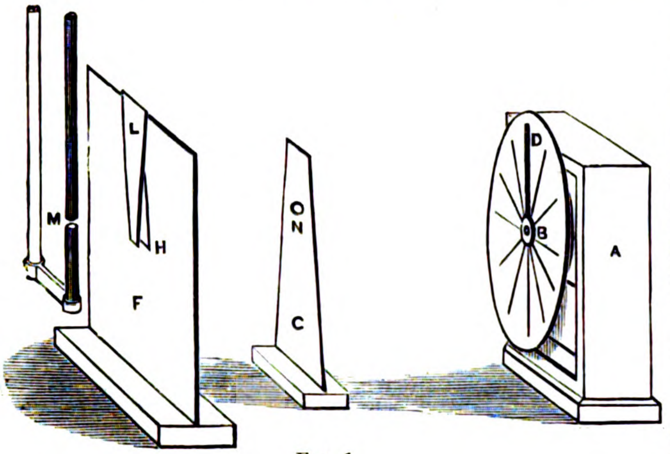


Fig. 1.

adjustable triangular opening, whose size can be varied by moving the piece L.

As the lower carbon burns down the image on D moves upwards. This causes the line to be traced in the form of a spiral, the distance between each turn being the length of the lower carbon burnt in an hour. The white lines left by the 12 brass wires divide the recording line into intervals of five minutes. This, along with the number of turns from the centre, enables us to know the exact time any particular feed took place.

The object of having the opening in F triangular is to regulate the amount of light passing through the lens, according as the image is projected at a greater or less distance from the centre of the registering paper, so that the resulting line traced shall have an equal intensity throughout, notwithstanding the paper moving more rapidly under the arc's image after the lamp has been several hours burning than it did at starting.

Thus it will be seen that the apparatus is perfectly automatic, requiring no further attention after the clock has been started and the image focussed; and it will register for more than eight hours if required.

Fig. 2 is a diagram taken by this instrument of a Brush lamp, and will show very clearly how every feed of the carbon, whether good or bad, is noted, as well as the time each feed took place.

The lens need not be halfway between the arc and the

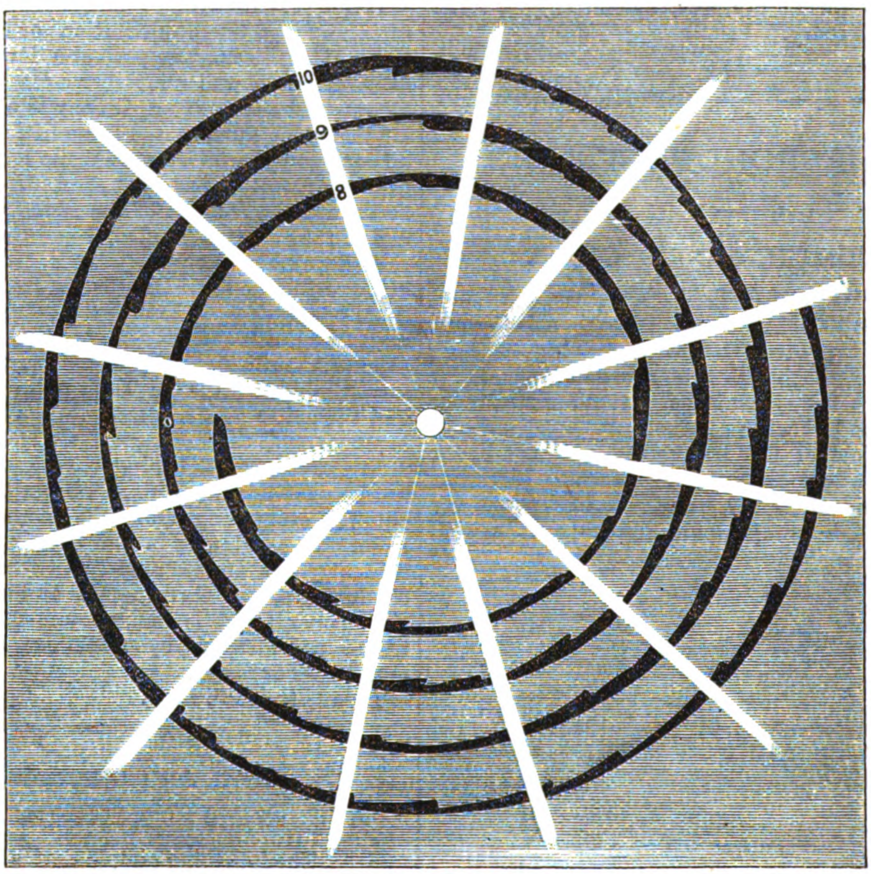

Fig. 2.

M is the arc lamp, a register of whose burning it is desired to take.

The lens stand C is placed 10 inches from the registering disc B, and an equal distance from the lamp M. F is placed about half way between M and C.

The height of the arc M is so adjusted that at starting its image on D is about an inch above the centre B, and the opening H L just allows the light to pass through the narrow upper part.

As the clock carries the sensitised paper forward under the image a line is traced the width of which exactly represents the length the arc had when that part of the paper was under the image, because the actinic power of the arc itself is so much greater than that of the white-hot carbon poles when taken horizontally that the latter have not time to imprint their images on the paper.

paper, so long as it is so placed that they occupy its conjugate foci. Fig. 2 was taken at a distance of seven inches from the lens, and therefore represents the burning of the lamp and the arc's length at about half their real amount.

For registering the burning of arc lamps in which both carbons feed, the lens would have to be slightly moved every hour, but in the majority of lamps now in present use only the positive carbon moves.

It will be obvious that a register thus taken must be far more reliable and useful than any statement of an observer, however careful he may be, besides being a great saver of labour and tedious watching, and if some such sort of registering were adopted at exhibitions or by manufacturers, the public would be far better able to judge of a lamp's steadiness than by merely seeing it burn for a few minutes. At Brighton, where there are between thirty and forty arc lamps

Digitized by Google

burning every evening, a great many of which are placed outside shops, and exposed to all weathers, every lamp is cleaned once a month, and no lamp is sent out of the testing room until its burning has been registered, and has given a better diagram than such a one as Fig. 2.

When the register is finished the paper is dipped in a weak solution of hyposulphite of soda, in order to fix the image, and when dry numbered and dated for reference if necessary.—Yours &c, ARTHUR WRIGHT.

Brighton.

THE SYPHON RECORDER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I desire through the medium of your valuable journal to call attention to a desideratum.

It is well known that since the publication of the *brochure* by Mr. J. C. Cuff in 1873 upon Sir William Thomson's "Syphon Recorder" nothing further, except a paper by Mr. James Alfred Ewing, published in 1876 by the Society of Telegraph Engineers, relating to the same subject has appeared in England.

The second pamphlet is admittedly a reprint of the first, with some few additions, embracing the latest improvements effected down to the date last mentioned.

Since the above dates, however, this beautiful instrument has undergone various modifications, both with respect to certain details of mechanism and its connections, which render the instructions of the above-named gentlemen less applicable. Indeed, the diagrams and plan of connections exhibited by them do not now correspond in many particulars with the present form of the instrument.

A French production has recently appeared by Mr. A. L. Ternant, which enters pretty fully into the latest developments of the above apparatus; but as many students, and more especially telegraphists, engaged in its manipulation are not acquainted with this language, they cannot avail themselves of the benefit of his manual, which, by all accounts, gives a lucid exposition of the principles governing the action of the instrument, and a clear explanation of its altered mechanism and connections.

Now, considering how extensively this instrument has been adopted, and the great favour with which it is received, I cannot help thinking that the want I have referred to should be supplied, and in order that it may speedily be met I have ventured to direct attention to the absence of a much-needed text-book.—Yours, &c., W. B.

Zante, 21st June, 1883.

GRAMME RING AND FIXING LINES OF FORCE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. W. B. Sayers has, I fear, misread my remarks on the above subject. What I said was that the product of E.M.F. and current (watts) in the external circuit was 100 per cent. greater with four poles than with two.

Mr. Sayers will see, therefore, that there is no necessity for me to explain how I got "1 per cent. of the normal E.M.F. when using one pair of magnets."

I need only add that when exciting one pair of field-magnets the other pair was removed.

As a supplement to the mode of fixing iron filings, showing the magnetic lines of force, described on page 98, perhaps the following method which I have found very easy and useful, may be of interest to some of your readers:—Fix a sheet of cardboard on a light wooden frame, and give it several coats of gum, allowing each to dry before applying the next. A good smooth surface is thus obtained. Place the card over the magnet and sprinkle the filings, tapping the card as usual to assist arrangement. As many of the filings will be vertical the card should be carefully lifted from the magnet, or if an electro-magnet be the subject of experiment, the exciting current may be stopped. Now gently direct a jet of steam on to the gummed surface, or subject it to a shower from a "spray producer." The gum being thus well moistened the filings sink in and are fixed. In lieu of a more orthodox arrangement a kettle with 3ft. or 4ft. of india rubber tubing will supply steam. Care should be taken to prevent the water which condenses in the tube from dropping on the card. This method is very useful when it is required to fix the curves over large magnets. Another way, not of fixing, but of printing the curves is to arrange them on a sheet of glass, and then gently place over them a sheet of paper moistened with gum and a solution of nutgalls, or starch paste and potassic iodide may be used. Very careful manipulation is required to obtain good results with this plan.—Yours, &c.,

July 2. W. M. MORDEY.

MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: My attention has just been called to the correspondence in your columns headed "Information Wanted, Medical Electricity." In my capacity as a public lecturer upon electrical subjects in numerous towns of England and Scotland I have been so often questioned upon this subject that I have latterly made it my business not only to gain all possible information about it from books, but also to commence a series of experimental investigations into the electrical resistance of various parts of the body, the most useful form of medico-electrical apparatus, the difference between the physiological effects of the continuous and the interrupted currents, and many other points. These experiments are still in progress, but Messrs. Sprague and Bennett, as well as others of your readers, may be interested to know that, at the request of the editor of *Health*, I am writing for that journal a series of articles upon the subject of medico-electric appliances, which will very shortly be commenced therein, and will be continued weekly. One object that I have in view is to expose some of the quack and sham appliances by which an ignorant public is being deluded.—Yours, &c.,

WM. LANT CARPENTER.

36, Craven-park, Harlesden, N.W., July 2.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you allow me to make a remark anent the letter of your correspondent, Mr. Sprague, page 159. Whilst rightly conceding to electricity curative virtues, and to magnetism little or none, Mr. Sprague regrets that "medical electricity has been too much left in the hands of a few medical specialists, and that no reliable scientific information can be gained."

I would call his attention to the following list of splendid works on medical electricity, published in England and abroad, wherein he will find much information on the subject, and learn that medical electricity has long since held an important and honourable position.—Yours, &c.,

THE INVENTION OF THE ELECTRIC TELEGRAPH.

It is always an invidious task, and sometimes a painful one, to have to weigh the claims of competing inventors. In deciding or discussing questions of this sort the most amiable qualities are often a snare to the arbitrator. He wants to be generous, he is anxious to redress a wrong, and in his haste he is apt to be over kind at somebody else's expense. This is especially the case where an invention which has established itself as a practical working system is afterwards found to have been foreshadowed or forestalled by some one whose efforts did not meet with like acceptance and a similar reward. To award honour where honour is due—a phrase we have heard a good deal of lately—is a very easy process, providing, first, we know where it is due, and, secondly—what is after all the main point—are quite sure as to the kind of honour we wish to award. Quite recently a discussion of this sort, not yet ended, has occupied the attention of people interested in the telephone; and now a still more exciting topic for disputation has been furnished in the interesting papers unearthed by Mr. Fahie relating to the invention of the electric telegraph.

The first instalment of Mr. Fahie's contribution on this topic will be found in another part of our present issue, and we are sure it will attract the notice its importance entitles it to. Our readers will peruse it with interest, and possibly with some of the enthusiasm manifested by the editor of the documents, an enthusiasm which will experience no abatement when the concluding portion of his communication, which we are compelled to hold over for another week, comes to be published. On the whole we would prefer to leave the question of priority, or honour, or whatever else it may be called, to the judgment of a discriminating public, at all events until the facts on the other side, if there are any, shall be made known. Some of our subscribers whose names have been associated with the electric telegraph from the very first may be able to throw some fresh light on the subject so far as it is a disputable one, and we shall gladly endeavour to afford space for any material contribution to the general stock of facts. All that we venture to deprecate is that spirit of partisanship which questions of this kind are so liable to develop. We may fully recognise and appreciate the value of one set of inventions without in the least forgetting our indebtedness to a set of another kind.

Our indebtedness has hitherto been thought to be due to Messrs. Cooke and Wheatstone. Their telegraph is a fact, and we Englishmen have as a rule ungrudgingly awarded them the distinction of being the first to establish the practicability of electrical signalling, without inquiring too nicely as to whether the ideas they contrived to work out were exclusively their own. Now and again we have heard it hinted that they got more credit than they were actually entitled to; but this, as we have observed in our opening remarks, depends upon the sort of credit we are disputing about. Probably Messrs. Cooke and Wheatstone's title to fame will not be much disturbed by these revelations concerning Mr. Davy, their contemporary and rival, for the insufficient but still practically effectual reason, that Mr. Davy's telegraph has not survived, whereas that of his competitors has. If the law of survival holds good in the world of invention as it does in the animal kingdom, then the telegraph we are now using is the fittest, and that which we have not used was less fit. On the other hand, several of his ideas have survived, or perhaps we should say have re-appeared, in very tangible shape since his time, though the man who gave birth to them fell out of the race.

To this extent Mr. Davy himself, who, we are glad to hear, is still living, and his champion, Mr. Fahie, would probably go with us. But the MSS. evidence now published relating to Edward Davy's early experiments goes farther than this, and outside it. These manuscripts, the authenticity of which is beyond all question, tend to show that the obscure occupant of 390, Strand, London, was not only an ingenious inventor, but a clear-headed and far-seeing man. Of his peculiar, and even wonderful, grasp of the properties of electricity there can be no question. One cannot help feeling as we read the highly suggestive notes and confident anticipations with which his memoranda and letters are crowded, that, had he remained in England to steer the destinies of the electric telegraph, it would have made more progress than in other hands it actually did make. What he accomplished was clearly the outcome of his own original mind; and what he predicted as possible, but allowed to be fulfilled by somebody else, belongs to him also. Whether anybody borrowed from him afterwards is another matter. All the circumstances considered, however, and looking back on the history of inventions generally, we, for our part, should say it would be extremely surprising if more than one person did not owe him much that has never been acknowledged. The early history of inventions, like the early history of nations, is very good fiction in its way; but the autobiography of in-

Digitized by Google

ventors would be far more edifying, and certainly more amusing.

In the slight autobiographical sketch put on record some forty-five years ago by Mr. Davy there is very little reticence and no want of candour—virtues not over common amongst the class of persons to which he belonged. It is evident, however, that he lacked virtues, one of which the inventor should never be without, namely, either money or business capacity. He appears to have exhibited his inventions before he patented them; and he lets us see plainly enough that he half suspected some of his visitors of trying to appropriate his invention, though he neglected the ordinary precautions against their doing so. It is satisfactory to know that he did get some slight return by his exhibition, though undoubtedly an inadequate one for his labours, but he failed to receive that reward which men of Mr. Davy's temperament value far more than hard cash, namely, public acknowledgment. That some meed of this much-prized award may now fall to his lot every candid reader of Mr. Davy's MSS. will sincerely hope; and on this account alone, if for no other, Mr. Fahie's historical notes will be heartily welcomed.

HONOUR TO WHOM HONOUR IS DUE!

EDWARD DAVY AND THE ELECTRIC TELEGRAPH, 1836 TO 1839.

BY J. J. FAHIE, MEMB. SOC. TEL.-ENGS. AND ELECS.

Few of our readers have heard of the name of Edward Davy in connection with the history of the telegraph, and for the sufficient reason that, beyond a few very short and very imperfect accounts* of a needle telegraph which he exhibited in London in 1837-38, and the patent for an electro-chemical recording telegraph, secured in July, 1838, nothing has been published regarding him and his early labours. Yet it is certain that, in those days, he had a clearer grasp of the requirements and capabilities of an electric telegraph than, probably, Cooke and Wheatstone themselves; and had he been taken up by capitalists, and his ideas licked into shape by actual practice, as they and theirs were, he would have successfully competed with them for a share of the profits and honours, which have so largely accrued to them as the practical introducers of the electric telegraph.

This, at all events, is the conclusion that we have come to, after the perusal of a number of most interesting MS. documents, which have been obligingly placed in our hands by Dr. Henry Davy, of Exeter, Edward Davy's nephew; and it is a conclusion which, we believe, our readers will cordially endorse when they have read the extracts from them, which we are now about to give. We feel a peculiar satisfaction at being thus the means of re-introducing to his countrymen one who deserves a most honourable recognition. Mr. Davy, we are glad to say, is alive and well, and, though now 77 years of age, is still following his profession, as a surgeon, in a far-off colony, whither, for reasons which need not concern us, he emigrated in 1839.

The idea of an electric telegraph first occurred to him about 1836, when he sketched out a plan to be worked by static, or frictional, electricity. We give it almost in the author's own words:—

Outline of a New Plan of Telegraphic Communication, by which Intelligence may be Conveyed, with Precision, to Unlimited Distances, in an Instant of Time, Independent of Fog or Darkness.

The agent is electricity, which is well known to pass through a conducting medium with the rapidity of lightning. The only difficulty is in the mode of applying it to the end proposed. Our method is as follows:

Let us suppose a number of copper wires, each covered with silk, and varnished, to be laid underground, side by side, from London to Liverpool. For greater protection, they may be enclosed in an iron pipe. If there be a small brass ball at each end of each wire, an electric spark applied to the ball at the London end of any of them might be drawn at the same instant from the corresponding ball at the Liverpool end.

If there be twenty-four such wires, there will be one for each letter in the alphabet; but six wires would be more than sufficient in practice, owing to the numerous changes that might be made upon them by combination. We will, however, suppose that there are twenty-four, for the sake of illustration, and that the intelligence is to be sent from London to Liverpool.

The questions, then, are—

1st. How the wires are to receive the signals in London.

2nd. How they are to deliver them in Liverpool.

A single letter may be indicated at a time, each letter being taken down by the attendant as it arrives, so as to form words and sentences; but it will be easy to see that, from the infinite changes upon a number of letters, a great number of ordinary communications [whole sentences] may be conveyed by a single previously concerted signal [consisting of one, or more, letters in a group].

Let *a*, *b*, represent one of the wires—*a*, the London end, and *b*, the Liverpool end. At *a*, is fixed a small metallic cup of mercury; *c*, *d*, *e*, is a bar of metal moving on a hinge at *d*, so that when the end *c*, is elevated, *e*, will dip into the mercury; *f*, is a chain, or wire, communicating with the prime conductor of an electrical machine, or with a powerful electroforus. The hinge, or pivot, *d*, may be continuous metal, and common to all the bars belonging to all the wires

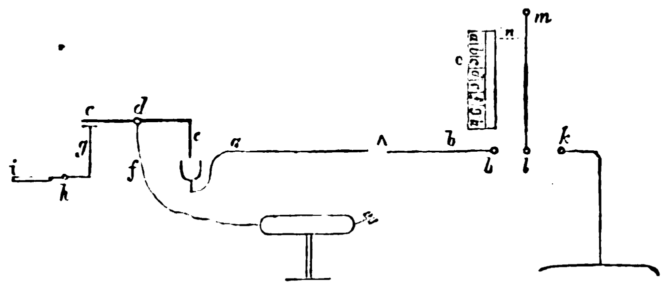

Fig. 1.

g, *h*, *i*, is made of glass, or partly of sealing wax, and turns on a hinge, or pivot, *h*, something like the key of a pianoforte. The pressure of the finger at *i*, will then raise *g*, and *c*, and depress *e*, which by dipping into the mercury will communicate the electric spark from *f*, to the wire *a*, *b*. This wire may stand for the letter *a*, and each of the others will be connected to a similar key apparatus, the same source of electricity sufficing for all.

At the Liverpool end is a small brass ball *b*, and *k*, is another, communicating by means of a metallic conductor with the earth; *l*, is a light [pith] ball suspended from *m*, by a rigid rod. When the electricity arrives at *b*, it attracts *l*, and immediately after repels it to *k*, where it discharges itself, afterwards resuming its normal position midway between *b*, and *k*. *o*, contains the letters ranged in a row, and each letter is connected to the rod of the corresponding electrometer by a stiff hair, as shown in the dotted line *n*. It is evident, then, that, at every movement of the rod towards *k*, the letter will be drawn from its place of concealment, and exposed to view in the open space above.

This, as Davy himself distinctly says, was not the plan that he would recommend in practice, and was described merely as an aid to a clearer perception of the principles involved. Accordingly, we find him, very soon afterwards, drawing up a proposal for a telegraph, based on the electro-magnetic properties of the Voltaic current.

This was to consist of as many line wires as there were

* *Mechanics' Magazine*, for January 20, and February 3, and 17, 1838; on which are based the very meagre and, of course, incorrect descriptions in all books on the telegraph. *The Penny Mechanic*, for February 10, 1838, and the *Morning Chronicle*, for January 25, and February 9, 1838.

Digitized by Google

letters of the alphabet. Twenty, he says, would have sufficed, or a still fewer number would do, by having recourse to the various combinations of which they would be, obviously, susceptible. Besides the letter wires, there was to be one for the alarum, and another for the return circuit, which was to be common to all. As to the *form* of the wires Davy says:—"Since the electricity is believed to move on the surface, and not in the substance, of a conductor, I conceive that where there is a long distance to travel, instead of wires, it will be preferable to use broad ribbons, such as would be obtained by passing a thick copper wire between the rollers of a flatting mill." *

Each ribbon, for its perfect insulation and protection, was to be varnished with shellac, then covered with silk or woollen, and laid in a slight frame of wood, well dried and varnished; or each ribbon might be bound from end to end with listing, saturated with melted pitch, or surrounded with caoutchouc, or with cloth saturated with this substance. All the ribbons, in whatever way insulated, were to be laid together underground in air-tight and water-tight pipes of iron or earthenware.

The best source of electricity Davy considered would be, either one of Daniell's constant-current cells, then just discovered, or, perhaps, a magneto-electric machine as constructed by Newman, or Clarke. The electricity so obtained was to be set in motion in any of the required wires by a set of keys, resembling those of a pianoforte, and connected to their respective wires in the way that we have just described. On pressing a key, its wire would dip into a cup of mercury connected with the source of, say, positive electricity, and thus a communication could be readily established, which would be instantly broken when the finger ceased to press on the key. The return wire was to be permanently connected to the source of negative electricity.

At the receiving end the signals might be indicated in various ways, in the adoption of one or other of which much, he says, would depend on the actual amount of electricity that would be available. Davy gave the preference to the following method:—Each line wire was to terminate in another of smaller size, formed into a rectangular coil of from five to two hundred turns, according to circumstances. All the coils were to be ranged in a row in the magnetic meridian, and in each was to be suspended a delicate magnetic needle. The whole was then to be covered by a board, the straight edge of which just concealed the needles in their positions of rest, but, on any of them being deflected, allowed one end to project, and so expose the letter marked upon it. The feeblest current, says Davy, would usually suffice to cause this deflection; but if, *from the great distance that the electricity had to travel, it became too feeble, its effect on the needles could be increased by multiplying the convolutions of the coils.*†

"The quantity of electricity," he goes on to say, "requisite to deflect a magnetic needle is so inconsiderable, that if the current of a moderately-sized pair of plates were sent into one end of a wire, and only one-hundreth part of it came out at the other end, it would still be sufficient. It is for this reason that I prefer the method just described, of indicating the signals, to others which occur to me, and which, as they may answer under certain circumstances, I will briefly describe:—

"1. A coil of wire from each conductor may be wound round a vertical glass tube, a light needle, or slip, of iron inserted in this tube will be lifted up while the electricity is passing through the coil, a letter fixed to the iron by a bristle will then appear above the lip of the tube, and be the signal. The only objection to this plan, in other respects the neatest and simplest, is, that the force of the current after passing a long distance may not be sufficient to raise the iron.‡

"2. On the same principle, a piece of soft iron may be surrounded by a helix of copper wire, so as to form a temporary magnet, which will attract and relinquish a small piece of iron carrying the signal letter at every make and break of the current.*

"3. Instead of steel needles, coils of copper wire may be deflected in the neighbourhood of fixed magnets, thus, *a*, *b*, are mercury cups, into which dip the line wires *c*, *d*, and the ends of the coil *e*, which are provided with steel points, and rest

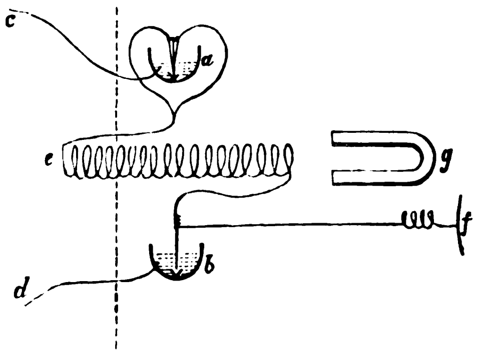

Fig. 2.

on agate surfaces, so that the coil can revolve with perfect freedom, a slender spring *f*, keeps the coil in its normal position of rest. During the passage of electricity in the coil it (the coil) will be subject to the influence of *g*, and be deflected."†

The alarum was to consist of a coil and needle, similar to those used for the letters, only that the needle was to carry a little fulminating silver card, which, on the passage of a current through the coil, was brought into the flame of a small lamp and exploded.

Davy concludes the document from which we have been quoting with a few words on the general question of conservancy, in which he says that the best situation for the lines would be along railways, where a number of men are constantly watching, and would prevent damage.

At short intervals, as every half mile, more or less, he would have a contrivance (not described), for ascertaining in what precise spot a fault existed, in case of any derangement of the wires. For this purpose the continuity of the copper was to be interrupted, and the two ends made to communicate by means of a cup of mercury. The places where these interruptions occurred were to be under lock and key in the possession of the surveyor.

According to the "Statement" which we find amongst Davy's MSS., giving the order in which his discoveries were made, he had not long finished the preceding paper when he saw how the number of wires might be reduced one half, by employing reverse currents to produce right and left deflections of each needle, each of which deflections could represent a letter. Other and very important improvements followed in quick succession, until, at the commencement of 1837, his ideas had not only assumed a really practical form, but his apparatus was so far complete that he was able to submit it to the test of actual experiment. For this purpose he obtained permission of the Commissioners of Woods and Forests to lay down a mile of copper wire, around the inner circle of the Regent's Park, through which, with the help of his friend, Mr. Grave, he performed many successful experiments.

Soon after this, in March, 1837, Davy appears to have been alarmed by the rumours which got abroad of Professor Wheatstone being engaged on an electric telegraph, and, in order to secure for himself a priority, he hastened to lodge a *caveat*, and, at the same time, deposited with Mr. Aikin, the Secretary of the Society of Arts, a sealed description of his invention, in its then state.

Davy now added the relay, or, as he called it, the "Electrical Renewer," which was the only thing wanted to make his telegraph complete and practicable, and the idea of which,

* It is but fair to mention that this and one or two others are the only cases of false reasoning to be found in all Davy's MSS.

† Cooke and Wheatstone, and Morse blundered painfully into a knowledge of this fact, of which Davy had thus early, 1836, so clear a perception.

‡ Here we have the axial magnet used in Royal House's Telegraph.

* Here we have the germ of the Morse Telegraph.

† Here we have the germ of the Brown and Allan relay. Davy says this plan is suggested on the possibility of steel magnets being influenced by the wrong wires, which might happen when all are close together in one parallel row.

Digitized by Google

it appears, occurred to him after a conversation on the subject of a telegraph, with a Mr. Bush of the Great Western Railway.

In May, 1837, Cooke and Wheatstone applied for their first patent, and to this Davy entered an opposition, lodging with the Solicitor-General, of the time, a full description of his own apparatus.* A copy of this important document is now before us, and as, when taken in connection with what we have already given, it shows, in a very clear way, Davy's position in May, 1837, we shall copy it *in extenso*, merely omitting a few preparatory remarks on the general principles of an electric telegraph, which, though necessary, because little understood, in Davy's time, need not now be repeated. We have also made a few verbal alterations here and there, which, while they in no way affect the sense,† will, we hope, render the writer's meaning more clear. A comparison of this paper with Cooke and Wheatstone's first specification will be a curious study, and, all things considered, will certainly not be to Davy's disadvantage.

Outline Description of my Improved Electrical Telegraph.

The parts of the telegraph may be divided into three, viz.:

1st. Signal and alarum arrangements.
2nd. Originating mechanism.
3rd. Conducting and continuing arrangements.

1. *Signals and Alarums.*

These are effected by a number of galvanometer needles, and conducting wires, each of which terminates in a double coil, which acts upon two needles. The form of the coil is that of the figure 8 (only the loops are made rectangular), and in each loop a magnetic needle is suspended. The whole is so arranged that all the needles point north and south. By means of pins, or stops, each needle is prevented from having its signal pole deflected except in one direction. It is then evident that if the electric current be passing in one direction the upper needle only, and, if in the other direction, the lower needle only, will be deflected. This method greatly obviates the objectionable vibration of such needles when suspended in the ordinary way, which vibration is a great impediment to transmitting the signals with sufficient rapidity of succession.

The needles are as follows, being altogether twelve in number:—

4 pairs of letter needles,
1 pair of colour needles,
1 pair of alarum needles.

Letter and Colour Needles.—The deflectable extremity of each letter needle bears three letters, A, B, C, and so on, each differently coloured, say, A red, B black, C white. Which of the three letters is intended for the signal is decided by simultaneously observing the colour needles, one of which has its deflectable extremity red, and the other black. If neither of the colour needles move, the white letter is the intended signal. By this plan the number of needles, and, consequently, of conducting wires, is reduced to the minimum consistent with convenience. One of the colour needles acting alone may, of course, convey some arbitrary meaning, according to the exigencies of the establishment.

Alarum Needles.—Of these only one is essential, so that the other is available for any other purpose required. The alarum needle is shaped so that a suitable piece of card, loaded with fulminating silver, may readily be slipped on to its extremity, which, when the needle turns, is carried round into the heat of a lamp constantly burning beside it. The card is to be renewed as often as it has been exploded, and a number are always at hand for the purpose. This alarum serves to call the attention of the person who is to watch the signals, and the same principle is evidently applicable to other purposes independent of the telegraph.

There are other modes of producing different kinds of alarums, which, by the application of the principle on which the electric currents are continued [*i.e.*, relayed], can be accomplished without difficulty.

II. *Originating Mechanism.*

This consists of—2 galvanic pairs of plates,
2 reversers,
4 pairs of communicating keys,
1 pair of colour keys,
1 pair of alarum keys.

One pair of plates and one reverser belong to the keys of the colour needles exclusively, the other pair of plates and reverser being common to all the other keys. As the action of the two reversers is the same, they may both be included under one description.

The Reverser.—The zinc and copper plates are, each, in communication with a separate cup of mercury, which we may call, severally, the zinc and copper cups. There are two wires, one of which we may call the common communicator and the other the return wire, each terminating in a double, or forked, extremity. To a wooden beam, capable of a certain degree of revolution on its axis, both of these forked pieces are fixed, so that if, in one position, the common communicator is in connection with the zinc cup, and the return wire with the copper cup, a partial revolution of the beam reverses the connections, making the wire from the common communicator now dip into the copper cup, and the return wire into the zinc cup. The reverser is actuated by every alternate communicating key.

The Communicating Keys.—These somewhat resemble the keys of a pianoforte. There is a pair for each wire. Pressure upon the first of each pair causes the point of the line wire connected with it to dip into a cup of mercury continuous with the common communicator, which enables us to establish, or cut off, in the most convenient way, the connection between the galvanic pair at one end, and the signal needles at the other. The second key of each pair, when pressed, turns the reverser before effecting the connection with the line wire, and, consequently, causes a reversed current to flow into the line.

The colour and alarum keys are operated in the same way

III. *Conducting and Continuing Arrangements.*

To command the signals not more than eight conducting wires will be required (probably less). All the letter and the alarum conductors, having, severally, formed their double coils, terminate in a cup of mercury from which a single conducting wire, called the return wire, reaches back to the originating station, where it is in connection with either the copper, or the zinc cup, according as the reverser may be set. The colour needles have a separate return wire*, as well as a separate reverser and pair of plates.

The best mode of laying the conducting wires remains to be determined by experience on a large scale, and the localities through which they may have to be brought. Either they may be somewhat flattened between rollers, and bound together with interposed pieces of cloth, soaked in pitch or rosin, &c., the whole being enveloped with canvas tarred, or impregnated with melted caoutchouc and linseed oil, or the like; or they may be secured in a tube (jointed laterally) of iron or earthenware. In the former case they would admit of *being suspended in the air, from post to post, protected by lightning conductors*, while in the latter they would be laid along, or underground; or they may be separately coiled round with cotton, and bound together, each being of a different colour for guidance in case of repairs.

As it may be more than doubted that an electric current in a circuit of great length, as between London and Dover, or London and Liverpool, would retain sufficient magnetic power to effect the signals after travelling so far, it may be

* Davy's case was backed by the evidence of several confidential friends, as Dr. Grant, Messrs. Thornthwaite and Hebert, and the mechanic who helped to make his instrument. We need not say how the Solicitor-General decided.

† We hope soon to be able to present all these valuable MSS. to the Library of the Society of Telegraph-Engineers and Electricians.

* Davy soon suppressed this, as he found that one return wire would suffice for *all*. He thus reduced the number of line wires to seven viz., four for letters, one for the alarum, one for the colour needles, and one return wire.

Digitized by Google

made to renew itself at given intervals, by the following self-acting contrivance:—

The Electrical Renewer.—The principle of this contrivance is that, the total distance being divided in a number of shorter ones, there be a separate galvanic circuit for each, and that, at the termination of each length of wire, its current be made to produce a motion, which establishes a communication between a fresh source of electricity and the wire which extends through the next succeeding distance. For instance, the first portion of wire terminates in a rectangular figure of 8-coil, fixed horizontally, so as to act upon needles, so suspended as to be capable only of vertical motion. Each needle is rendered incapable of motion except in one direction, so that one, or the other, will be deflected according to the direction in which the current is passing. At the end of each needle is fixed a cross piece of copper wire, whose ends are turned downwards. One of these ends is constantly immersed in a cup of mercury, which is connected with one of the plates of a galvanic pair, while the other end dips into a second cup of mercury every time the needle is deflected by a current in the coil. This second cup is the commencement of the next circuit.

To complete the circuit, a corresponding but reverse connection must be made with the return wire, so that while the needle of the signal wire establishes a communication with the zinc, that of the return wire establishes simultaneously a communication with the copper, and *vice versâ*.

By this contrivance it is clear that there can be no physical limit to the distance to which electric currents may be carried; and, therefore, the expense of long distances will cease to be in an increased ratio to that of short ones.

Additional Observations.

(1). The coils herein described may be either simple, or multiplied, as the case may require. It will probably be better that they should be multiplied, than that the needles should be too delicately suspended.

(2). For stopping more effectually the vibration of the needles immediately on their relapse, on the cessation of the current, the following plan is proposed:—A portion of the wire is coiled round a small piece of soft iron, which is rendered magnetic during the passage of the electricity, its polarity varying with the direction of the current. This is so arranged that the end of the needle bears against it, and is held by it, when no current of electricity is passing, or when it is passing in one particular direction, and that, when passing in the other direction, the iron will be so polarized as to repel, instead of attract, the point of the needle.

(3). There is a variety of modes in which different kinds of alarums may be made, when once the principle of the Electrical Renewer is applied, as there is then no limit to the power which may be obtained, and it requires little reflection to suggest a multiplicity of methods of making this power produce sound. A piece of soft iron may be rendered alternately magnetic and non-magnetic, so as to withdraw, when required, the peg of an alarum clock, &c., or a needle may be made to carry round a red hot wire, or match, so as to explode a cannon, &c.

(4)*Portable Telegraphs.*—Such a contrivance might occasionally be useful in warfare. The conductors should then be made in short lengths, each conductor differently coloured for facility of distinction.

(5) *Marine Telegraphs.*—Communications may be effected through, or under, the water by enclosing the conductors in ropes well coated, or soaked, in an insulating and protecting varnish, as melted caoutchouc, &c. The ropes could then be sunk to a certain depth by weights, and supported by small floats, or buoys. In connection with the rope we may have an air-tight and water-tight electrical renewing apparatus [*i.e.*, Relay] at each requisite interval.* On this subject further experiments are necessary.

(6) Land telegraphs may, of course, be made to indicate similar signals and produce similar alarums at numerous places at the same time.

* As in Van Choate's patent No. 156 of January 19, 1865.

(7) Estimated expense of particular lines of communication at £70 per mile, which includes two sets of wires for communicating in each direction.*

From	Miles.	£
London to Dover	71	5,000

	£3,000

which, including Sundays, is about £10 per day; and this, divided by 3, gives £3 6s 8d. as the sum necessary to be received, on an average per day, at each station, in order to pay expenses and return an interest of 5 per cent. for the outlay.

(9) *Capabilities.*—The telegraph constructed on the plan herein described is capable of transmitting about fifty letters in two-and-a-half minutes, but, by an improvement devised subsequently to writing the early part of this description, they may be sent several times as rapidly. In fact, the only limit now appears to be the quickness with which the eye can catch the letter, and the hand note it down.

During the summer and autumn of 1837, Davy effected some important changes in the mode of making the signals. In the plan just described the needles were made to turn horizontally, and the eye was obliged to attend to two movements, at the same time, in order to distinguish by the colour needle, which of the three letters was meant. The oscillation of the needles in settling down to their positions of rest caused a waste of time, and was otherwise a bar to rapid signalling. By the following plan both these disadvantages were obviated without introducing fresh ones:—

The needles were all suspended, somewhat like balance beams, so as to turn vertically, instead of horizontally, and they were made long, so that their ends might describe large arcs, although the movement at the centre might be small. The letter ends were weighted so as, under ordinary circumstances, to dip under cover, but, on the passage of a current, they were raised, so as to bring the letters opposite an illuminated sight groove.

What used to be the colour needles were now provided with small screens, which could be raised, or depressed, in front of the letter needles, so as to conceal, or expose, them at pleasure. Thus, if the letter needle bearing A B C were shown, and neither of the distinguishing needles moved, their screens would lay so as to cover A, and C, B, only being visible. If now one screen, say the top one, were deflected

* It is not that Davy did not know how to make his apparatus reciprocating, so that one set of wires should suffice for to and fro correspondence, but because, as he explains in other places, he thought that when once the telegraph was established there would be more traffic than one set of wires could carry; and he, therefore, recommends here, as elsewhere, the laying down at once of an *up* and *down* set of wires, for exactly the same reasons that we have *up* and *down* lines of railway.

Digitized by Google

it would cover B, and expose A, and, similarly, if the other screen were moved it would expose C, and cover B.

In this arrangement the eye had to watch only one signal, and, as all the letters could be arranged more compactly, the field of view was greatly reduced, and the letters could be easily caught and noted down, without the necessity of even turning the eyes.

The next alteration was in the same direction of simplification and perfection of the signalling apparatus, and was a decided improvement even upon the last. It consisted in making the letters immovable, and covering them by three screens in such a way as to be able to expose any desired

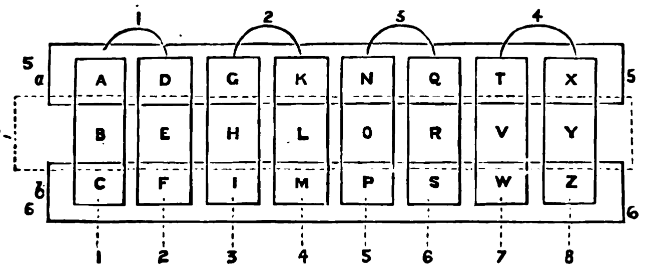

Fig. 3.

letter at will. Fig. 3 shows the arrangement. 1, 2, 3, 4, were pairs of screens, which, when at rest, covered all the letters, ranged in rows of three behind them, and one, or other, of which, in each pair, could be moved aside, according to the direction of the current in the line wire to which it belonged. The screens 5, 5, and 6, 6, answering to the colour needles of the old plan, but now called *triplicators,* were so arranged as, in their normal position, to cover the top and bottom rows of letters, and, on the passage of a current in their coils, to move inward and cover the centre row.

If, now, any one of the letter screens, say that on the extreme left of the figure, were moved aside, only one letter, B, would appear; because A, and all the letters in the top row, would be covered by the triplicator 5, 5, and C, and its fellows in the bottom row, by the triplicator 6, 6; but if one of the triplicators, as 5, 5, had been simultaneously moved, then only the letter A, would appear. Thus, a single movement of a letter screen will expose any letter in the centre row, and a combined movement of a letter screen and a triplicator will exhibit any letter in the top, or bottom, row according to the triplicator employed.

But, as each wire was to be provided with a separate battery, and as the currents could be sent in one direction, or another, in one, or more, wires at the same time, it is clear that one to four letters could be shown at once, *provided* they were all in the same row, and were not covered by the same pairs of screens. Thus, the word B O Y could be signalled at once, by sending, say, a positive current into the first wire (on the left), exposing B, a positive current into the third wire, exposing O, and a negative current into the fourth wire, exposing Y. Again, the word A N T could be shown at once, by sending a current into the triplicator wire, so as to cause the screen 5, 5, to move down, then a positive current sent into the first, third, and fourth letter wires would uncover the letters A, N, T, respectively. In this way, besides being able to show all the letters of the alphabet singly, about 200 different groups of letters could be displayed at one operation, which, by having certain meanings attached to them, would greatly expedite a correspondence.

The needles by which the screens were actuated were, as before, suspended in the manner of ordinary balance beams with horizontal axes; but these axes were now prolonged, and carried tall upright rods, at the free ends of which the screens were fastened. Thus, the slightest movement of the axes produced a considerable deviation of the screens, while their extension permitted of the needles (with, of course, their coils) being placed at sufficient distances apart to prevent their mutual disturbance.

In the working model which Davy had constructed for exhibition all the letter-indicating mechanism was enclosed in a mahogany case, which could serve also as a desk for writing down the signals as they appeared. In the front of the case there was an aperture about sixteen inches long, and three or four inches wide, and this, at ordinary times, was so dark that difference of surfaces of the screens could not be detected, which led to the deception that only one screen was used—a deception which the author purposely planned and encouraged, in order that the *modus operandi* of his instrument might not be divined, which would prevent him taking out a patent for it afterwards, as he contemplated doing.* Behind the screens was a plate of glass, covered with black card-board, out of which spaces, representing the letters of the alphabet, were cut, and behind the glass was a white card-board, on which the light of a lamp was thrown. The result was that, whenever a screen was turned aside, a beautifully white letter appeared to the spectator at the aperture.

A working model, embodying all the author's improvements to date, was shown about November-December, 1837, at the Belgrave Institution, London, and from the great interest which it there excited, Davy resolved upon a more public exhibition; accordingly, he rented a room for one year in Exeter Hall, and there installed his telegraph from December 29, 1837, to November 10, 1838.†

A writer in the *Mechanics' Magazine*, for February 17, 1838, thus describes the exhibit. It will be observed that, for the reason which we have given above, his language in places lacks clearness, but this is of little consequence, for we, who are now in the secret, can easily follow him:—

DAVY'S ELECTRICAL TELEGRAPH.

Sir: The favourable notice of your correspondent, "Moderator,"‡ on the subject of Mr. Davy's electrical telegraph, induced me to visit Exeter Hall, for the purpose of carefully inspecting the invention; and I am enabled to bear testimony to the general accuracy of your correspondent's remarks, and also of the great pleasure I experienced in the investigation of the apparatus. Under these circumstances I beg to offer a few additional remarks, in some measure corrective of those made by "Moderator."

As a preliminary observation, I would suggest to the inventor the necessity of removing to some other part of the building, or, if that cannot be accomplished, of quitting the place altogether, and locating himself in some situation where his light may not, literally, be "hid under a bushel." He appears to be surrounded by rooms under repair or alteration, and his delicate apparatus is, consequently, smothered with dust; the room is also small, dark, and altogether of most unpromising appearance.

In front of the oblong trough, or box, a lamp, described by your correspondent, is placed, and that side of the box next the lamp is of ground glass, through which the light is transmitted for the purpose of illuminating the letters. The oblong box is open at the top, but a plate of glass is interposed between the letters and the spectator, through which the latter reads off the letters as they are successively exposed to his view. At the opposite side of the room a small key board is placed (similar to that of a pianoforte, but smaller) furnished with twelve keys; eight of these have, each, three letters of the alphabet on their upper surfaces, marked thus, A. D., and so on. By depressing these
B. E.
C. F.
keys in various ways the signals, or letters, are produced at the opposite desk as previously described. How this is effected is not described by the inventor, as he intimated that the construction of certain parts of the apparatus must remain *secret*. By the side of the key board there is placed a small galvanic battery from which proceeds the wire, twenty-five yards in length, passing round the walls of the room. Along this wire the shock is passed, and operates upon that part of the apparatus which discloses the letters, or signals.

The shock is distributed as follows:—The under side of

* This little *ruse* explains the fogginess of all accounts of Davy's telegraph hitherto published. See foot-note on page 181.

† Davy's MSS. See also *Mechanics' Magazine*, for January 20, 1838, and "The Electric Telegraph Company *versus* Nott and others," Nott's and Grano's affidavits. The room occupied by Davy was that known as No. 5, for which he paid rent at the rate of £35 per annum.

‡ Correctly, "Moderatus," in *Mechanics' Magazine*, for February 3, 1838.

Digitized by Google

each signal key is furnished with a small projecting piece of wire, which, on depressing the key, is made to enter a small vessel filled with mercury, placed under the outer end of the row of keys. A shock is instantly communicated along the wire, and a letter, or signal, is as instantly disclosed in the oblong box. By attentively looking at the effect produced, it appeared as if a dark slide were withdrawn, thereby disclosing the illuminated letter. A slight vibration of the (apparent) slide occasionally obscuring the letter indicated a great delicacy of action in this part of the contrivance, and, although not distinctly pointed out by the inventor, is to be accounted for in the following manner:—When the two ends of the wire of the galvanic apparatus are brought together over a compass needle the position of the needle is immediately turned at right angles to its former one; and again, if the needle is placed with the north point southward, and the ends of the wire are again brought over it, the needle is again forced round to a position at right angles to its original one *(sic)*. Thus it would appear that the slide, or cover, over the letters is poised similarly to the common needle, and that, by the depression of the key, a shock is given in such a way as to cause a motion from right to left, and *vice versâ*, disclosing those letters immediately under the needle so operated upon.

A gentleman present hazarded a doubt as to the shock being energetic enough for a considerable distance. The inventor replied that he was in possession of means that would enable him to convey intelligence to any distance that may be required. Whether this was to be effected by *coils* of wire at intervals was not stated; such, however, appears to me a reasonable supposition. The difficulty of *tubing* for the protection of the wire was discussed. I took the liberty of suggesting the employment of a proper-sized *tobacco pipe tubing*, which was received with satisfaction. It was also stated by a gentleman present that he was in possession of a smaller battery than that at Exeter Hall, and had obtained from it a power equal to *forging* iron plate; it will, he said, be shortly produced.—Yours respectively [*sic.*],

CHRIS. DAVY.

3, Furnival's-inn, Feb. 5, 1838.

(TO BE CONTINUED.)

BOYS' ENGINE POWER METER.

We have often pointed out that an electrical engineer should have the education and experience of a mechanical engineer, as well as the special knowledge of electrical subjects. He must not only know such methods of measurement as enable him to deal with E.M.F., current, resistance, &c., but must be quite as familiar with dynamometers, indicator diagrams, and so on. Any instrument, then, that is designed to simplify these measurements is of interest to electrical engineers. Mr. Boys claims to have designed a simple apparatus that will do all and more than the ordinary indicator, with an expenditure of less labour to the user. The instrument is manufactured by the Electrical Trading Company, who have issued a descriptive pamphlet as to the theory, construction, and practical applications of the meter. We understand that the instrument is used with very satisfactory results by Messrs. Nettlefolds, the India Rubber, &c., Works, and others.

This meter is designed for the purpose of directly measuring and recording the work done by steam, gas, water, and hot-air engines. The instrument, instead of merely indicating by a diagram the variation of effective pressure during only a single stroke of the piston, and leaving the result to be subsequently interpreted, shows clearly at a glance, the actual working efficiency of an engine during any particular stroke it may be desired to observe. It does more than this, it automatically and continuously registers the total work done from the moment the engine is started till it is stopped.

With the exception of the power meter the machines at present in use for measuring the work done by an engine are all modifications of the well-known indicator invented by Watt and improved by Richards. A diagram must be taken, and the area of the diagram has to be computed.

In the meter of Mr. Boys this computation is effected continuously by ingenious but simple integrating mechanism, and recorded with precision upon a dial, from which the result may be read off at any moment. Although Mr. Boys' meter differs very widely in its general principles from any existing indicator, it resembles, in several fundamental points of its construction, the ordinary Richards machine. Indeed, a very fair notion of its leading features may be obtained by imagining that the pencil and supplementary link-work of the indicator is replaced by a single arm carrying a small wheel which presses upon a cylinder so arranged as to slide longitudinally upon its axis and yet rotate therewith. The remarkable effect of the ingenious contrivance by which this idea is carried out is, that instead of merely tracing a diagraphic figure with a pencil—and for only one stroke of the engine—the machine, in accordance with certain mathematical principles, becomes at once a meter, which, without really drawing the figure, actually measures its area from instant to instant, adds up the results continuously—presenting the total upon a dial after the manner of a gas meter.

Fig. 1 shows instrument open, with diagram attachment.

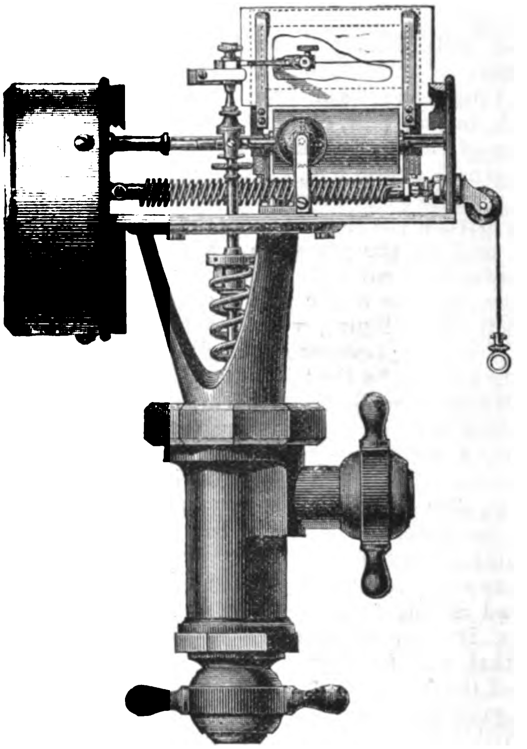

FIG. 1.

A spiral spring around a piston rod attached to the piston within the cylinder are the parts somewhat similar to the indicator. A horizontal cylinder slides longitudinally upon an axial rod, but keyed thereto, so that axle and cylinder must revolve together. A tangent wheel, turning upon the pivots of a crutch that moves upon a horizontal axis, is kept pressed upon the cylinder by a spring, so as to be always in rolling contact with the surface of the cylinder. An arm in the plane of the tangent wheel, and perpendicular to its axis, passes through a pivot attached to the end of the piston rod. The displacement of the meter piston (= the effective pressure on the engine piston) is measured by the tangent of the angle through which the plane of the wheel is rotated; for which reason this wheel has been appropriately called the "tangent wheel." The integrating cylinder is carried in a frame which moves to and fro with the piston of the engine, being pulled the one way by a wire, and the other by a spring. By this arrangement the continued reciprocation of the integrating cylinder with that of the engine piston is ensured, and the velocity of the one kept at every instant proportional to that of the other. So long as

Digitized by Google

the tangent wheel is horizontal, and therefore in the same plane as the axis of the integrating cylinder—that is, so long as the tangent wheel occupies its normal position—the reciprocation of the integrating cylinder will be unaccompanied by any rotation about its axis; but should the meter piston be displaced by ever so small an amount, the plane of the tangent wheel will be at once inclined to its normal position, and therefore to a straight line on the surface of the cylinder and parallel to the axis that passes through the point of contact of the tangent wheel. The immediate result of this will be to cause the integrating cylinder, as it reciprocates in contact with the inclined tangent wheel, to turn upon its axis—the surface of the cylinder passing under the tangent wheel in a screw line. Clearly enough, the greater the inclination of the tangent wheel the greater will be the rotation of the cylinder; but, in the absence of a clear knowledge of the mathematical relation between the amount of the rotation of the integrating cylinder and the two other factors of the problem furnished (1) by the inclination of the tangent wheel, and (2) the rectilineal displacement of the integrating cylinder, no valuable practical application of the idea could possibly be made. What, then, is the law of this relation? It is remarkably simple, and may be stated briefly thus:—The amount by which the integrating cylinder rotates is directly proportional to the product of its rectilineal displacement into the tangent of the angle of inclination of the tangent wheel—which angle is, of course, the complement of the angle of the screw line forming the path of the tangent wheel on the surface of the integrating cylinder. But, inasmuch as the rectilineal displacement of the integrating cylinder is, by the nature of its connection with the engine piston, proportional to the motion of the latter, and the tangent of the angle of rotation of the tangent wheel proportional to the displacement of the meter piston, which displacement, being opposed by the resistance of a spiral spring, measures the effective pressure of the engine piston, it follows that the amount by which the cylinder rotates is rigidly proportional to the product of the pressure in the engine piston into the distance through which it is moved. This, however, measures the work done by the engine, and therefore the amount of rotation of the integrating cylinder is an accurate measure of the available engine power.

The following is the practical mode of using the instrument, as described in the pamphlet referred to:—

The meter is connected with the engine somewhat similarly to a Richards indicator by pipes and taps of large bore. The lower end of the meter cylinder should be placed in communication with the end of the engine cylinder opposite the piston rod, and the upper end connected with the corresponding end of the engine cylinder by means of union joints. The steam being turned off by means of the cocks, a suitable spring must be screwed into its place in the meter, and the union joint at the neck loosened so that the top may be turned easily into a convenient position. Remove the cap of the meter and attach a piece of fine piano wire, by means of a loop, to the terminal hook of the spring band, which will be found fastened to the integrating cylinder. The other end of the piano wire must be properly attached to some moving part of the engine, so that as the piston rod reciprocates the integrating cylinder may be caused to move to and fro with it through the space of about $1\frac{1}{2}$ inch. Turn the back of the upper part of the meter towards that portion of the engine to which the wire is attached, so as to let the pull come straight on the band, and lengthen or shorten the piano wire, so that the saddle of the integrating cylinder is not bumped against the bearings of the shaft which carries it. The instruments allow of nearly two inches play, so there ought to be an easy $\frac{1}{4}$ inch on each side. Next let the engine draw the integrating cylinder to and fro several times, so as to push the sliding collars to their extreme position, and then measure accurately the distance between them and determine n. Assume, for example, that $n = 1{\cdot}41$ inch, and that M, or the engine stroke, $= 20$ inches. Then $\frac{M}{n} = \frac{20}{1{\cdot}41}$. Taking $D = 15$ inches, and $s = 150$, and inserting these values into the formula that presents the value of a complete revolution of the meter cylinder, we get

$$\frac{M}{n} \times \frac{\pi a l s D^2}{12 d^2} = \frac{20}{1{\cdot}41} \times \frac{3{\cdot}1416 \times 1 \times 1 \times 150 \times (15)^2}{12 \times (1)^2} = \text{foot}$$

pounds of work for one revolution of the meter cylinder or x units as shown on the dial. Now, x, π, a, l, and d are fixed when the instrument is made, and may, therefore, be replaced by a constant, c. Thus the actual working formula is simplified at once, and becomes $\frac{M}{n} \times D^2 s C$. Every meter has the value of C accurately computed and confirmed by a practical test, and then marked in the lid of the box for reference. s, the value of the spring, is carefully tested in each case, and stamped upon it before being sent out. All, therefore, that remains to be done by the person who first sets the instrument to work is to find the values of M, n, and D, as stated above. These are M, the stroke of the engine in inches, D its diameter, also in inches, and n the longitudinal motion of the

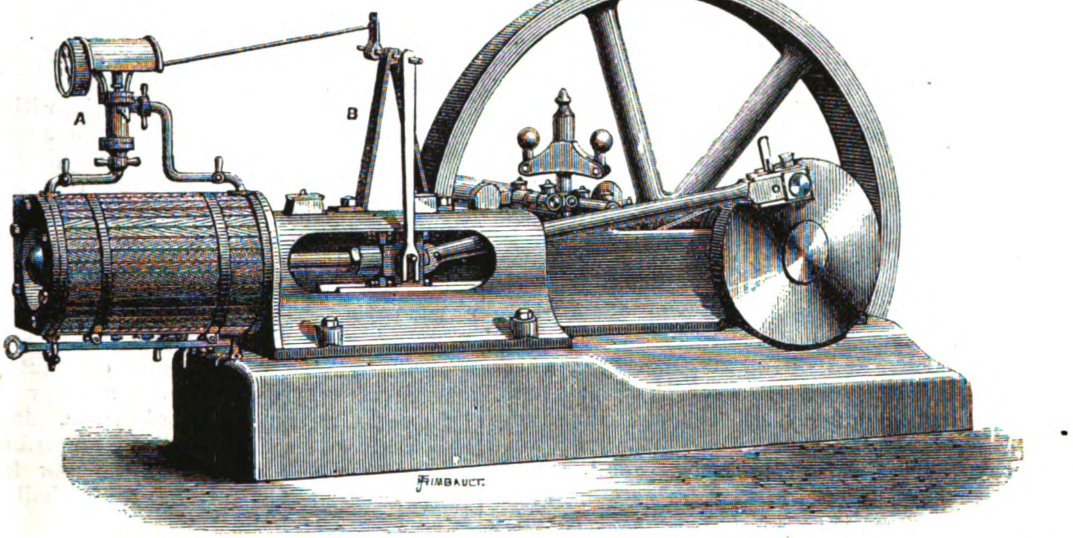

FIG. 2.—Showing Boys' meter (A) fitted to a horizontal engine, in a position similar to that of an ordinary diagram indicator. The supports and arms (B) connecting the meter with the piston rod of the engine are exactly the same as those used with the ordinary indicator in general use.

Digitized by Google

integrating cylinder. The formula $\frac{M}{n} \times D^2 s C$ will then give without further trouble the value in foot-pounds of the meter unit for the particular engine to which it is applied.

Once obtained, this number is absolutely fixed, and if it is desired to know how many foot-pounds of work have been done during, say, the day's run of the engine, we have merely to determine the recorded units, as in a gas meter, and multiply the number by this constant. For the average horse-power of the day the number of foot-pounds must, of course, be divided by 33,000, and by the time in minutes, or the number of units run in a minute multiplied by the value of the meter unit, and the product divided by 33,000 will give the true horse-power. The result would not, of course, in this case, be such a fair sample of the engine's work as that deduced from a day's or week's run—but it would be infinitely better than the horse-power deduced by an ordinary indicator for a single stroke.

The following easy rules are all that are necessary to observe in the practical use of the meter:—

1. To determine the number of foot-pounds of work done in any given time:—Note the number of units shown on the dial at the commencement and end of the period, subtract the one from the other, and so find the units run during the time. This number, multiplied by the meter unit, gives the foot-pounds of work done by the engine during the interval.

2. To determine the horse-power of the engine at any particular time:—Note the units run in a minute, or the average per minute during a number of minutes, and multiply by the foot-pound value of the meter unit. The product divided by 33,000 will be the horse-power.

Every engine has its own constants easily determined as above; but, if desired, the meter will be specially constructed at a small extra cost for giving foot-pounds direct, or so that the units read off in a minute give horse-power; but this is not recommended, as for this purpose it would be necessary to send the constants of the engine with the order, and no real advantage secured.

The care of the instrument requires that all the working parts should be slightly oiled occasionally, except the surface of the integrating cylinder and of the tangent wheel, which should be kept as clean as possible. The gilt spring should be sometimes examined, wiped dry, and cleaned with an oily patch.

When at work the instrument presents several notable points of interest. For example, when "cushioning" exists the index goes back a little at each stroke, showing negative work. Also, if the steam is suddenly turned off, so that the engine continues in motion only from the inertia of its moving parts, the negative work done is recorded on the dial by a backward motion of the index. The instrument, in fact, is perfectly accurate, showing only the real effective work of the engine, and not imaginary estimates of its possible power.

ON THE PENTANE STANDARD, AND ON A NEW FORM OF PHOTOMETER.*

BY A. G. VERNON HARCOURT, M.A., F.R.S.

It is no longer necessary, in addressing an audience familiar with photometry, to preface the account of a proposed standard of light with a statement of the defects of the existing standard. That sperm candles of six to the pound, burning 120 grains (more or less) per hour, may give from 1-15th to 1-18th of the light given by five cubic feet of common gas supplied hourly to a London argand, the standard changing while the quality of the gas supposed to be tested by it remains unchanged, was proved long ago. The strength of a chain is the strength of its weakest link; and there is something ludicrous in the pains we bestow upon all the details of photometry, providing for a most exact comparison between our carefully-manufactured gas and a standard which goes up and down as we look at it. We English are apt to be credited with skill and care in matters of technical science; and probably no industry better deserves this credit from our neighbours than the manufacture and supply of coal gas. It happens, consequently, that letters are received from time to time by the metropolitan gas referees, from some colonial or foreign authority, asking for information as to our method of estimating the illuminating power of coal gas, which they are sure will be of great value for their guidance. They are not pleasant letters to answer. One has to choose between communicating the details of the apparatus and the elaborate precautions we prescribe (smiling the while at the little good it will do them); or, on the other hand, avowing that our careful and costly system of photometry is valueless because we use a fluctuating standard.

Two remarks as to the causes of the variation of candles may here find a place—one relating to the wicks, the other to the place in which they are burnt. Many of us can remember back to the days of snuffers, and the dimness which came on as the candle-wicks grew longer, and the sudden brightness which came from the application of the snuffers. The chief cause of the unequal light given by one standard candle and another lies in the greater or less perfection of the self-snuffing which the curvature of the wick produces. For the same consumption of sperm, the light given by two candles will be widely different of which one has a wick bending over through a right angle within ¼in. of the cup, and keeping the cup full of melted sperm, while the other has a thick loosely-plaited wick standing up about ½in. within the flame. The second cause of variation is the greater or less movement of air in the room or other enclosure within which the candle burns. Some trials on this point have recently been made at the Cheltenham Gas Works, with the result that the same candles tested alternately in a small room with no more space than the photometer requires and in each of two good-sized rooms with ordinary ventilation, burnt in the latter case about 120 grains per hour, and less than 110 grains in the former case. The light of the candles was not measured; it varies in such cases with the consumption, but in a much greater degree.

In 1877 I brought before the Chemical and Physical Sections of the British Association a method of producing a standard flame from a gas of constant composition and a burner of very simple construction which gave the same light as the average standard candle. It is to a proposal for substituting this standard flame for ordinary sperm candles in photometry, and also to the new form of photometer which stands at the entrance to the hall, that your attention is now invited.

An account of the pentane standard is given in the paper to which reference has been made, and a further account in a letter to the Board of Trade, printed two years later, as well as in the subsequent report of the committee on photometric standards. But as the standard has not been brought under the notice of the Gas Institute, and is not widely known, it may be well to describe the manner in which it is produced and may be reproduced anywhere and at any future time, at least until the petroleum wells have run dry.

The liquid used for the preparation of the standard gas is the most volatile portion of American petroleum, obtained by first purifying the "gasoline" of the air gas companies by agitation with oil of vitriol and with solution of caustic soda, and by then rectifying the product by repeated distillation till the whole passes over at a temperature of 120deg. Fahr. The liquid thus obtained consists of nearly pure pentane—a hydrocarbon bearing the same relation to amyl alcohol, or fousel oil, which marsh gas bears to ordinary alcohol, and having the formula $C_5 H_{12}$. It vaporises more quickly than ether, and has the indispensable property which ether has not of being insoluble in water. Its purity can readily be tested by weighing a measured quantity. Calling water 1,000, the specific gravity of pentane at 60deg. is between 628 and 631. Its vapour is 2½ times as heavy as air. A convenient quantity of the standard air gas to make at one time is 4 cubic feet. This is made by drawing into a small gasholder 3 cubic feet of air, and then discharging into it a pipette holding 9 cubic inches of pentane. In a few hours the gas is made; and since the rate of burning is half a cubic foot per hour, and a testing does not occupy more than five

* A paper read before the Gas Institute.

Digitized by Google

minutes, the gas thus made will serve for nearly 100 testings. The volume of vapour which adds itself to the 3 cubic feet of air as the pentane vaporises amounts to 1·05 cubic foot, and if the experimental gasholder gives the means of reading the volume of its contents, the reading of the increase in volume serves to show whether the gas has been rightly made. An account of experiments upon the effect of small variations in the quality of the pentane and in the proportion of air is to be found in the papers to which reference has been made, showing that with moderate care no appreciable variations in the standard flame are likely to arise from these causes.

From the gasholder the standard air-gas passes through a small meter and governor to the burner, which consists of a brass tube 4in. in length and 1in. in diameter, plugged with a disc $\frac{1}{2}$in. in thickness, through the middle of which is drilled a $\frac{1}{4}$in. hole. Gas issuing under a pressure which no gauge would show is apt to burn unsteadily, and to protect the flame with a chimney would, to a small extent, affect the light, partly by interception, but chiefly because imperfection in the glass, otherwise imperceptible, may cause a slight convergence or divergence of the rays. But it is found that a flame almost as steady as that of a candle is obtained by making the flat top of the burner four times as wide as the orifice, and by placing a chimney round the burner to guide the air currents which rise from the heated sides of the burner and form an invisible chimney.

The air-gas must be turned up or down till the flame touches, without passing, a fine wire stretched $2\frac{1}{4}$in. above it. If the height of the flame be carefully adjusted, small variations in the quality of the gas, and consequently in the rate at which it burns, may be made without affecting appreciably the amount of light sent forth by the flame; and even large variations, made purposely, have been found to produce a relatively small effect. But the rate of burning will generally be found to lie between 0·48 and 0·52 cubic foot per hour.

By many trials and a gradual adjustment of the quality of the air-gas and the height of the flame, the standard has been made to correspond to the average of a number of sperm candles. How far the attempt to produce a constant standard of light representing the ideal sperm candle has been successful it is not for the writer to say; but he may be allowed to quote the verdict of the committee on photometric standards:—

"*Sec.* 4.—Compared with the sperm candle, Mr. Harcourt's air-gas flame is exact and trustworthy as a standard of light. We have had before us Mr. Harcourt's letter of April 8, 1879, addressed to the Board of Trade; and his statements, both with regard to the untrustworthiness of the sperm candle, to which we have already referred, and to the advantages of the air-gas flame as a standard of light, are entirely borne out by our investigations. The flame is not subject to the chief sources of variation which affect the amount of light emitted by a sperm candle, and those variations to which it is subject are under the control of the operator. . . . The extreme difference obtained by two observers in 19 determinations, by Mr. Harcourt's method, of the illuminating power of a specially-stored coal gas was 0·3 candle, or 1·8 per cent.

"*Sec.* 5.—The further question of the relation of Mr. Harcourt's air-gas flame to the variable candle standard having been referred to us for determination of the Board of Trade, we have made the comparison by determining the average illuminating power of a specially-stored sample of coal gas alternately by means of the standard candles (as at present supplied to the official testing places) and by the air-gas flame. The average illuminating power of the coal gas, according to the sperm candles, was 15·99 candles for the fortnight the experiments lasted. According to the air-gas flame the average illuminating power of the coal gas during the same period was 16·02 candles. Thus we found the average value of the sperm candle to be practically identical with the light given by the air-gas flame."

The committee proceed to recommend that for the determination of the illuminating power of coal gas the use of the sperm candle should be discontinued, and that for the future the air-gas flame should be employed instead, as a means of affording with constancy the light of one average sperm candle.

But the recommendation of a committee is without effect, unless either the old standard is abolished and a new standard substituted by Act of Parliament, or those who carry on unofficial testings for their own information are persuaded that the plan recommended is worth a trial. The Board of Trade have been prevented by the block in the House of Commons, which has suspended many more important measures, from bringing under the notice of Parliament the question of a change in the standard of light. Until a change has been sanctioned, candles must be used in all official testings made under the Gas Works Clauses Act. But, in the meantime, the adoption at gas works of a mode of testing which would give at any time the true value of the gas, would both supply useful information as to the effect of any change in the coal or the mode of working, from day to day, and from year to year, and would also furnish evidence whenever an unfavourable return by the official tester was due to some eccentricity in the candles used. Mr. Hawksley says that, since more gas than formerly is extracted from a ton of Newcastle coal, the illuminating power of the gas must be less, no matter what the number of candles to which it is found equal; and, in the absence of any trustworthy standard by which the gas of the present day can be compared with the gas of ten or twenty years ago, it must be admitted that the evidence of photometry is worth very little in the matter.

(TO BE CONTINUED.)

PRACTICAL TELEPHONY.

(CONTINUED FROM PAGE 166.)

TWO OR MORE BELLS ON ONE CIRCUIT.—Where it is necessary to have two or more bells on one circuit, it is a very great advantage to be able so to arrange them that the ringing

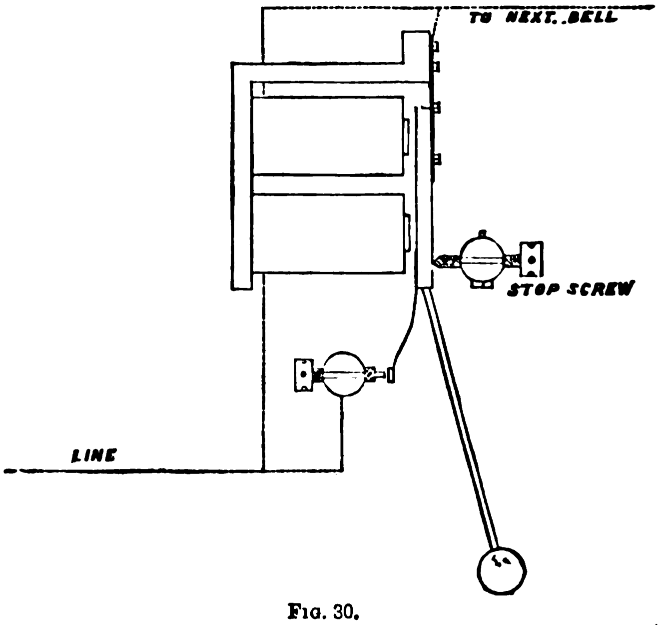

FIG. 30.

of one will not interfere with the ringing of the other. This is usually attained by employing one vibrating and the remainder single-stroke bells, the whole being in series. A much better plan is to place the bells (all vibrating) in series, and each bell should govern its own vibrations, not by breaking the circuit, which would interfere with all the other bells, but by shunting its own coils. This leaves the circuit closed for the other bells. Directly the armature falls back the coils are put again in circuit, and the armature attached. This method is shown by Fig. 30. The remarks for adjusting bells apply in exactly the same manner to extra bells, which are merely ordinary electric bells. For telephonic work the bell coils should have a resistance of about 30 ohms; when in good order and properly adjusted the bell should ring well through a resistance of 70 ohms, using four batteries of four cells.

SWITCHES AND THEIR APPLICATIONS.—Switches must be

Digitized by Google

placed amongst the most important of the appliances used in telephony. Not a single station can be fitted up without a switch in some form, either automatic or worked by hand as required, whilst an exchange or switch room, as its name implies, may contain as many as a thousand, or even more. It will be sufficient for our purpose to group switches into two classes, viz.,

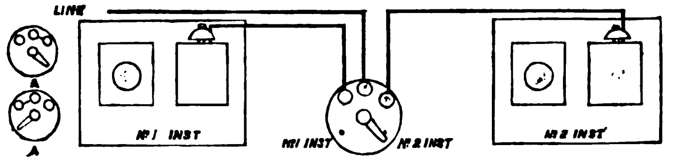

Fig 31.

those used by subscribers and those used in the switch room by the operators.

Switches used by Subscribers.—The purposes to which switches are applied in this case are connecting two or more

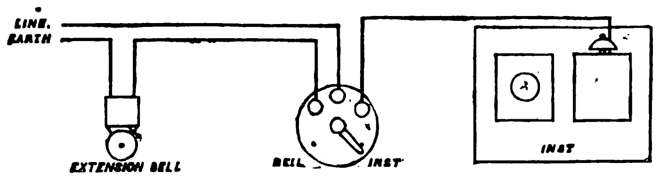

Fig. 32.

lines to one instrument, two or more instruments to one line, or connecting an extra or extension bell, as it is called, to ring at some distance from the instrument, as the various requirements of the subscribers demand. They are also used to prevent subscribers making an illicit use of lines or apparatus.

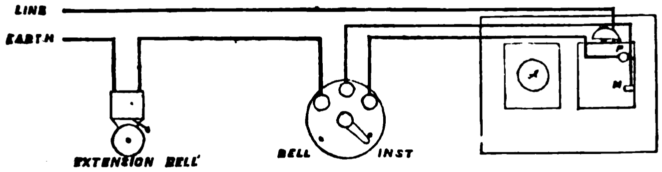

Fig. 33.

Three Point.—The simplest form is that known as the Three Point, Fig. 31. When connected, as shown in this figure, one line can be connected to either of two stations, one situated near the switch, the other at any required distance; for instance,

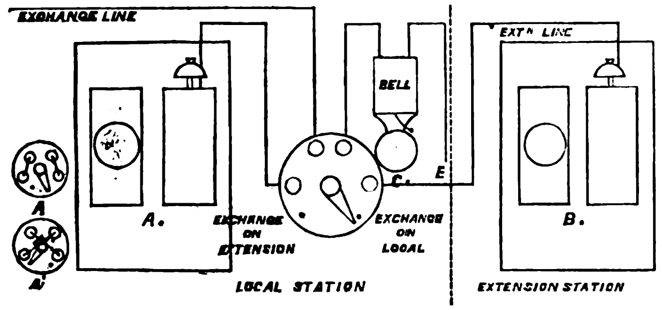

Fig. 34

another office or a medical man's bed room. Fig. 32 shows connections for a single line and instrument, the switch being near the instrument and an extension bell, which may be placed where it can be better heard, for night use,

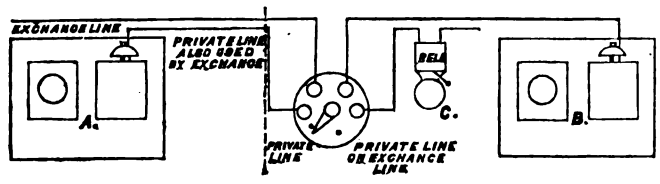

Fig. 35.

&c. When thus arranged the switch must be turned to instrument side before the call signal can be answered. When done the handle must be again turned to bell side. Fig. 33 has been successfully adopted by the writer to obviate the necessity of moving the switch. When turned to bell side, the line goes direct to line terminal as usual, the centre or handle terminal on switch is connected to bracket M or its equivalent, the right hand terminal on switch to bell post P, the wire ordinarily connecting M and P must be removed (see also Fig. 25, p. 136). The switch then acts only on the bell, and speaking can be carried on without moving the switch. A A′ shows the passage of current through switch according to direction of handle.

Four-point (commutator) Switch.—This switch, Fig. 34, is used, connected as shown, in the case where an exchange line extension is used, and where it is required to prevent the exten-

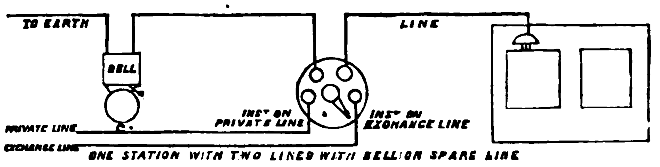

Fig. 36.

sion being used as a private line between the two instruments A and B; at the same time it allows the bell C to be rung, to indicate that the extension station desires to communicate with the exchange. The handle should be kept to the right. Fig. 35, the switch, connected as here shown, enables a private line to be used as part of an exchange line, but prevents the instrument nearest the exchange being used for speaking to the exchange. Instrument A is at the distant end of the private line. B the instrument switch and bell at the end of private line nearest exchange. When the handle is to the right, A is in direct communication over the private

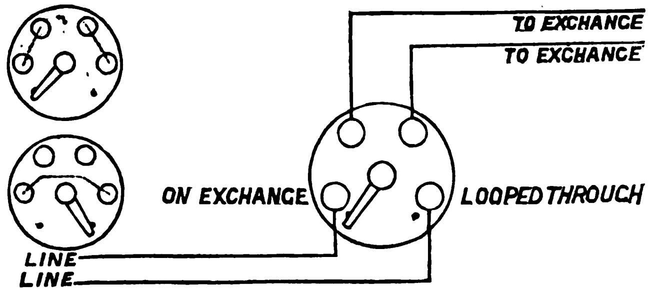

Fig. 37.

line to the exchange, when to the left its normal position A and B can then communicate over their private line, and should the exchange call the extra bell *c* rings. B must then move the switch to the right. A can then answer the exchange. Fig. 36 switch connected as here shown, enables one instrument to be used for both exchange and private lines. When the private line is to instrument, the bell C is on exchange line, and *vice versâ*. At the same time, the two lines cannot be put through. Fig. 37 switch connected for a battery commutator.

Six Point.—Fig. 38 shows the connections for the original

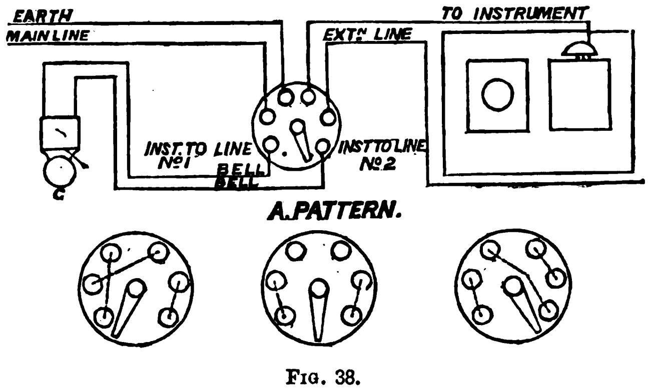

Fig. 38.

pattern six point. It is used on an extension of either a private or exchange line. When the handle is to the right the intermediate and extension instruments are connected, and calls from main line, are received on the extra bell *c*; when to the left the intermediate is connected to main line, and the extra bell *c* to extension line; and, lastly, when the handle is in the central position, the main and extension lines are connected, the intermediate instrument is cut out, but the bell *c* is inserted in the circuit so that the intermediate station can be signalled to disconnect. To illustrate the use of this the intermediate station

Digitized by Google

can be in the clerk's office. They then answer the calls: if important, they can ask the principal if he will speak to the person calling. If he wishes to do so, the switch is placed in the central position, and the clerk's office cut out. When the communication is finished, the clerk's office is signalled to replace the switch into its normal position. Fig. 39 is merely the latest

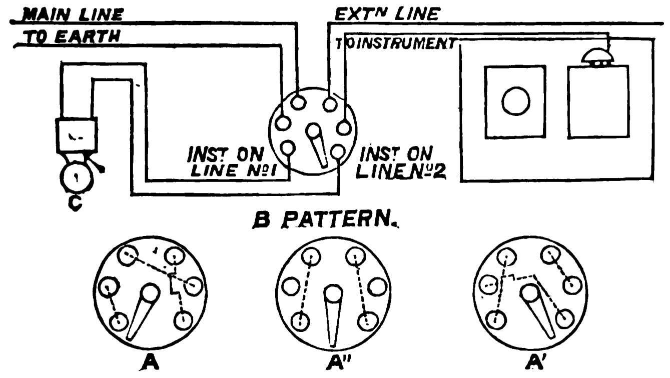

Fig. 39.

pattern switch connected up to correspond with the change of internal connections. Its action is precisely the same.

A A' A'' shows the passage of the current through the switch; the handle has three positions, left, right, and central.

(TO BE CONTINUED.)

LONDON AND GLOBE TELEPHONE AND MAINTENANCE COMPANY (LIMITED).

The second ordinary general meeting was held at St. Michael's Hall, George-yard, Lombard-street, on the 4th inst., under the presidency of Mr. Stewart Pixley.

The Secretary (Mr. J. Ford) having read the notice convening the meeting,

The Chairman said: Gentlemen, although the present meeting is in fact the second ordinary general meeting of the Company, it is, as regards the present shareholders, their first meeting. The Company was registered in January, 1882, and the first or statutory general meeting was held in due course. Thus this meeting becomes a second ordinary meeting. The capital of the Company was not subscribed until the end of August, 1882, and the shareholders will doubtless remember the strenuous efforts made by the United Company by advertisements to discourage intending subscribers. These were not successful, as you know, and an allotment was made towards the end of August last. This period being in the height of the holiday season was not favourable to immediate action. Moreover, the Postmaster-General's license had not been obtained, because it was known that he would only grant his license to a responsible corporation with a sufficient capital. Mr. Eldred's experience as a telephone constructor for carrying on the operations of the Company in regard to establishing exchanges in the metropolis and developing the business generally was very valuable. In this connection it may be mentioned that Mr. Eldred has had a vast experience in America in telephone business, most of the early telephone exchanges in different parts of the United States having been planned and carried out by him. I visited America in the autumn of last year, and whilst there took considerable pains to inquire into the nature and character of telephone business as carried on in the United States, and it will be sufficient for this purpose to say that the result of my inquiries convinced me that telephone business in this country is still in its infancy. Mr. Eldred wanted to go away for a short time to the United States, but as soon as he returned active operations were commenced, with a view to establishing the Company's telephone business, although at that time the Postmaster-General's license had not actually been granted, but it was understood the Company would secure it. The license was not, in fact, signed until the 31st of January last, but between the date of Mr. Eldred's return and the date of the license satisfactory progress had been made in arranging routes and obtaining way leaves for the metropolitan exchanges of the Company. The shareholders probably have but little conception of the difficulty encountered in running overhead wires in a large city like London. Telegraph wires of different descriptions have been run from time to time either by public companies or private individuals, so that it requires the greatest skill and management to secure routes for new wires. The public, too, have been uneasy with regard to these wires, and as it is, of course, necessary to erect fixtures on houses to carry the wires, this uneasiness has made the task of obtaining way leaves and the right to fix poles one of additional difficulty. These difficulties have, it is believed, been in great part overcome, but not without very considerable delay and a not inconsiderable expense, a large staff having to be organised and employed to secure to the Company the rights and privileges they required. The result is that at the present moment the Company are the owners of rights or way leaves numbering considerably over 1,000, they have erected over 400 poles, and run several hundred miles of wires. Offices have also been secured for the exchanges, and the connecting up of subscribers with such exchanges has already commenced, and the directors believe that in a very few weeks they will be able to show a subscription list which will not do discredit to the exertions which have been made. Whilst on the subject of wires and way leaves, it is proper to refer to the difficulties which have been met with in this respect at the hands of the United Telephone Company. It is with considerable reluctance that the directors have referred in their report to the opposition this Company has met with from the United Company. There is ample room in this great metropolis, much more in the United Kingdom, for half a dozen telephone companies to carry on a lucrative business; but the United Company, for reasons best known to themselves, have from the very outset not only put every difficulty in the way of the promoters of this Company, but of the Company itself, after its capital was subscribed, in doing business. The object of this opposition is now plain. The United Company have determined, if possible, and at any expense, to strive for a monpoly of the telephone business in the metropolis. As soon as the United Company found this Company establishing its routes and lines for exchanges, it did all in its power to oppose and obstruct the Company in its operations. With regard to way leaves it may be summed up in a few words, that in every possible instance the United Company have tried to block out this Company's lines, and prevent available routes from being secured. This opposition, carried as far as the criminal prosecution of this Company's assistant general manager and some of its servants, has not succeeded, and the directors have good reason to be satisfied with what has been done by their construction manager in these respects, and to regret only that opposition which has been met with has been productive of more delay than was anticipated. More recently the United Company have made attempts to prevent this Company from using any telephone instruments whatever. These attempts have failed, because the directors believe they have sufficient instruments to answer all purposes for some considerable period, and the directors trust the shareholders will now day by day hear of increased activity with regard to the Company's business and daily increase in the number of subscribers to the Company's exchanges. That the Company have yet difficulties to contend with the directors do not desire to conceal. The recent litigation commenced by the United Company against this Company—three Chancery actions having lately been launched by the United Company—must be contested, and the rival company will doubtless, if they carry out their opposition in the spirit in which it has hitherto been conducted, use every opportunity of harassing this Company, by litigation or otherwise, regardless of consequences, and in the hope that the proceedings will embarrass the action of this Company and thereby secure the monopoly which the United Company are endeavouring to obtain. The directors would remind the shareholders that telephone business is of a somewhat novel and very peculiar character. It takes time to develop, but with patience and means at command the directors believe that success must eventually attend the efforts of this Company, and having regard to the small amount of capital upon which this Company has to pay a dividend, compared with the enormous capital of rival companies, success in this case, in the view of the directors, means a most remunerative income and large dividends. To arrive at this successful result, however, the directors call upon the shareholders to rally round them, and not only to support them in the difficult enterprise in which they are engaged, but to use their influence in every direction to increase the number of subscribers of the Company, bearing in mind that every additional subscriber often carries with him a number of others, and that when the lines are once established and the exchanges are opened additional subscribers means additional profit at a comparatively small additional expense.

Mr. Robert Ewing seconded the motion.

Mr. Jackson inquired why the meeting was held on the 4th of July, seeing that the accounts were made up so far back as the 31st of December?

The Chairman, in reply, stated that the Articles of Association of the Company provided for the accounts being made up to December 31. They would have been very willing to hold the meeting many weeks ago if they could have done so, and they had been very anxious to hold it in order to relieve the shareholders' minds of anxiety. Everything was going on very well.

The election as a director of Mr. Jocelyn T. F. Otway was afterwards confirmed, and the auditors—Messrs. Chatteris, Nichols, and Chatteris—were re-elected.

THE BRUSH ELECTRIC LIGHT AND POWER COMPANY OF SCOTLAND (LIMITED).

An extraordinary general meeting of this Company was held at St. Michael's Hall, George-yard, Lombard-street, on the 5th inst., for the purpose of considering, and, if deemed desirable, passing the subjoined resolutions:—

1. "That the capital of the Company be reduced from £300,000, divided into 60,000 shares of £5 each (of which a first issue of 8,000 shares of £5 each, fully paid, and 22,000 shares of £5 each, with £2 10s. called up thereon, has been made), to £245,000, divided into 38,000 of £5 each, and 22,000 shares of £2 10s. each, and that such reduction be effected by reducing the liability upon each of the 22,000 shares by the sum of £2 10s., being the amount uncalled thereon."

2. "That the 8,000 shares of £5 each be sub-divided into 16,000 shares of £2 10s. each."

3. "That the 30,000 shares of £5 each at present unissued be sub-divided into 60,000 shares of £2 10s. each."

The Earl of Crawford and Balcarres presided.

The Secretary (Mr. Frederick M. Brocklebank) read the notice convening the meeting.

The Chairman referred to the legislation in connection with the electric light, and stated that the action of the Government in taking up the Electric Lighting Bill had, in his opinion, placed hampering conditions on what was going to be a most flourishing trade in this country. When he last addressed them they had applied for provisional orders for starting work in the four principal towns of Scotland—Glasgow, Edinburgh, Aberdeen, and Dundee. The requirements of the Board of Trade were peculiar, requiring a coalition, as it were, between the companies and the municipal authorities before anything could be done, and before the Board of Trade would issue what was called a provisional order. With the utmost efforts on the part of the directors, they had not been able to meet the requirements of the municipal authorities of Glasgow, Edinburgh, or Aberdeen; and it was their duty not to acquiesce in terms which would have made it impossible for them to work at a profit. After excessive trouble, they had been able to obtain from the Board of Trade the Dundee Lighting Act, and

Digitized by Google

they hoped to proceed immediately with this provisional order. They considered they ought to be able to make a good thing out of it. They would lose no opportunity of trying to push the matter as far as they could in connection with private enterprise. They had decided to submit the resolution before them at the instance of shareholders. The directors had ample funds for carrying out the work before them. No further provisional orders could be obtained this year; but they had given notice of their intention to apply next year for provisional orders for no less than fifteen towns in Scotland. He concluded by moving the first resolution.

The Hon. ASHLEY PONSONBY seconded the motion, and expressed his belief that if the gas companies had had anything like the trouble and annoyance which the electric lighting companies had, there would have been no gas-lighting yet, but only oil and tallow candles.

The MANAGING DIRECTOR (Mr. Dickson), in reply to questions, said the provisional order for Dundee was for fifteen years.

The Hon. A. PONSONBY added that the order enabled the company to enter into a contract with the Dundee authorities, but there was no contract yet.

The SOLICITOR stated, in further reply, that he could not anticipate that there could be the least objection legally to the resolutions.

The CHAIRMAN put the motion, and declared it carried by more than a three-fourths majority; and, after some further discussion, the other resolutions were also passed.

THE EASTERN TELEGRAPH COMPANY, LIMITED.

Report of the directors for the half year ended 31st March, 1883, to be presented to the twenty-second half-yearly ordinary general meeting, to be held at the City Terminus Hotel, Cannon-street, in the City of London, on the 12th day of July, 1883, at one o'clock:—

The directors submit the accounts and balance-sheet for the six months ended 31st March, 1883. The Company's revenue for this period amounted to £328,404 14s. 11d., from which are deducted £87,827 1s. 10d. for the ordinary expenses, and £50,901 6s. 3d. for expenditure relating to repairs of cables, &c., during the half year. After providing £1,943 14s. 3d. for income-tax there remains a balance of £187,732 12s. 7d., to which is added £56,836 7s. 6d. brought from the preceding half year, making a total of £244,569 0s. 1d. From this amount there is deducted £22,479 16s. 8d. for interest on debentures, £20,297 4s. 5d. for dividend to 31st March, 1883, on the preference shares, and £85,000 placed to the general reserve fund, leaving a balance of £116,791 19s. The directors have during the half year paid an interim dividend of 2s. 6d. per share on the ordinary shares for the quarter ending December, 1882. They now recommend the declaration of a final dividend for the year ended 31st March, 1883, of 2s. 6d. per share, and a bonus of 1s. per share, both payable on the 14th inst., making, with the three previous payments on account, a total distribution of 12s. per share, or 6 per cent. for the year on the ordinary shares. The balance of £2,791 19s. shown at the foot of the revenue account is proposed to be carried forward to the next half year. The general reserve fund, after adding the interest received during the half year, now amounts to £537,889 10s. 5d.; this, with the special reserves stated on the balance-sheet, makes the total amount of reserves £569,823 0s. 6d. The revenue includes £14,479 12s. 1d. net receipts for the half year upon the company's shares in the Eastern and South African Telegraph Company. The reserve funds of that company now amount to £155,520 4s. 5d., and in addition the sum of £54,220 16s. 8d. is held by the trustees of the sinking fund for redemption of debentures. The revenue account also includes £2,600 dividend for the half year on the shares of the Black Sea Telegraph Company belonging to this Company, by which the line is worked and maintained under agreement. The various sections of the Company's cables are in good working order, and the Company's repairing ships are in efficient condition. The sum of £10,000 has been taken from the ships' maintenance fund in part payment for the ss. "Volta," as intimated in the last report. The whole cost of this vessel and outfit will be charged to the depreciation fund. The new vessel has already proved herself both economical and efficient. The triplicate cable between Suez and Aden, referred to in the last report, was successfully laid by the Telegraph Construction and Maintenance Company on the 21st of April last. The new line is working satisfactorily. In accordance with the agreement entered into with the Suez Canal Company, reported to the last meeting, the land line connecting the Company's cables at Port Said and Suez has been completed and is now in full work. In pursuance of the special resolutions passed last year, the directors have decided to issue £500,000 Four per Cent. Mortgage Debenture Stock for redemption of debentures falling due in October next, and other capital purposes for which the stock was authorised. As the Company's debenture stock constitutes a first charge upon the entire undertaking and revenue, the directors confidently recommend it as an investment.

Telegraph Construction	33½,	34½	34½	33¾
India Rubber, Gutta Percha, and Telegraph Works	30½,	31½	31½	31½

A TELEGRAPH ENGINEER will shortly require a RE-ENGAGEMENT as MANAGER of Cable and General Insulated Wire Works. Gutta Percha and India Rubber Core; Military, Torpedo, Electric Light Cables and Leads; I.R. Cut Sheets, &c.; G.P. Surgical and other Sheets, &c.; Spreading. Sixteen years' experience in principal firms. Can provide complete instructing staff, mechanical and electrical. Terms inclusive. Any part of Europe. Address, in first instance,
"G. P.," care of Harding, Cocks, and Co.,
29, Jewry-street, Fenchurch-street, London.

A GOOD SECOND-HAND DYNAMO MACHINE REQUIRED. State full particulars, with price, to C. E. C., 110, Cannon-street, E.C.

WANTED, TWO or THREE (or more) GERMAN WORKMEN or STUDENTS to join with advertiser in any part of London in READING DYNAMO MACHINE LITERATURE. No expenses.—Address J. W., 21, Herbert-street, New North-road, N.

WANTED.—Volumes VII., VIII., and IX. of "THE ELECTRICIAN." State cash price and condition to RENNICK, KEMSLEY & Co., 4, Finsbury-circus, London.

DYNAMO, lights six 15 c.-p. Swan Lamps, £8. Larger sizes made. Experiments conducted for inventors. OPPERMANN BROS., Electric Light Engineers, Brewhouse-yard, 172, St. John's-street, E.C.

CARBONS.—For all kinds of ELECTRIC LIGHT,
Leclanché, Bunsen, and Grenet Batteries,
Telephones, &c.
The best, cheapest, and most reliable for every kind of Lamp.
Carbons of any size, shape, and of every description manufactured to order at the shortest notice.
JAMES W. COLUMBINE,
2, Carlisle-street, Soho-square, W.

TENDERS WANTED to SUPPLY the ARC LIGHT
for ST. JAMES'S HALL, BURNLEY.
Gas engine and about 40 Lights.
To be sent to THOS. BELL, Architect, Burnley.

TURKISH PATENTS.
NOTICE TO PATENT AGENTS AND INVENTORS.
The undersigned having established a special agency in Constantinople, are prepared to SECURE PATENTS in TURKEY for all inventions not yet in use in that country for £35, including drawings of average amount.
Special terms to Patent Agents.
W. P. THOMPSON and CO.,
BRITISH and INTERNATIONAL PATENT AGENTS,
6, LORD-STREET, LIVERPOOL
(and 323, HIGH HOLBORN, LONDON).

FAURE-SELLON-VOLCKMAR ACCUMULATORS.
On and after 1st January, 1883,
THE
ELECTRICAL POWER STORAGE COMPANY
(Limited),
4, Great Winchester-street Buildings, E.C.,
will be prepared to supply
FAURE-SELLON-VOLCKMAR ACCUMULATORS.
Which can be used in conjunction with any Incandescent Lamp or Electrical system, and afford the only reliable and economical means of Lighting Private Houses, Hotels, Theatres, Ships, Railway Carriages, &c., by Electricity.
Particulars and prices post free on application.

INSULATED ELECTRICAL WIRE, Silk, Cotton, or India-rubber covered. Conductivity guaranteed. German Silver Wires for Resistance. Braided Handle Cord, Silk Cord for Electric Bells, &c.—WILLIAM RICKARD, Derby London Agent (stock kept), EDWIN HOLLOWAY, 2, Gutter-lane, E.C.

NOTES.

THE EASTERN EXTENSION COMPANY.—The Eastern Extension Telegraph Company notify that their Madras Penang cable is now repaired.

ELECTRIC RAILWAY AT BRIGHTON.—At Thursday's meeting in last week of the Town Council sanction was given to erect temporarily a short electric railway on the beach.

SOUTH KENSINGTON MUSEUM.—The directors of the Electric "Sun" Lamp and Power Company have undertaken to light the galleries at the South Kensington Museum by the "Sun" Lamp.

THE NEW PRESIDENT OF THE ROYAL SOCIETY.—At the meeting of the Council of the Royal Society on Thursday week Professor Huxley was chosen president in place of the late Mr. Spottiswoode.

ELECTRICAL EXHIBITION AT VIENNA.—Lord Sudeley, Sir William Thomson, Sir William Siemens, and Sir F. Abel, C.B., have been appointed British Commissioners for the Electrical Exhibition to be held at Vienna in August.

OPTICAL TELEGRAPHY.—M. Adam is endeavouring to establish a system of optical telegraphy between the islands of Réunion and Maurice, a distance of 245 kilometres. His preliminary experiments have proved satisfactory.

THE EASTERN TELEGRAPH COMPANY.—The Eastern Telegraph Company notify the repair of the Zanzibar-Mozambique cable, thus restoring telegraph communication with the East Coast of Africa and the Cape of Good Hope.

TELEGRAPH LEARNERS.—We understand that at the preliminary examination for male telegraph candidates which took place a fortnight ago before the Civil Service Commissioners about thirteen hundred applicants presented themselves.

THE WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts for the week ending 6th July, 1883, were £1,870, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRICAL ACCUMULATORS.—According to *L'Electricité* Messrs. M. J. Arnould and B. Tamine have invented a new accumulator, the performance of which is said to be very remarkable, but the particulars of its construction are not yet made public.

ELECTRIC LIGHTING OF THEATRES.—The Theatre Gymnase, in Paris, will be lighted by electricity on the 1st September; the work of installation has already commenced, and is framed on the model of the system adopted in some English theatres.

ROYAL AGRICULTURAL SHOW.—We understand that the grounds at York will be illuminated by nine Crompton arc lamps of from 4,000 to 6,000 candle-power, the lamps being supplied by current from a Bürgin dynamo, driven by a Marshall and Sons engine.

THE EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of the Eastern Extension Australasia and China Telegraph Company for the month of June, 1883, amounted to £34,307, and to £31,122 for the corresponding period of 1882; increase, £3,185.

A STEP BACKWARDS.—The Moor Iron Works Company, of Stockton, after a three years' trial of the electric light, have, it is stated, abandoned this system of illumination, and have resorted to the old mode of lighting by gas. The change has been made for purely economical reasons.

A SELENIUM REGULATOR.—The property which selenium possesses of conducting electricity more readily when in a bright light than when in comparative darkness has been turned to account by Signor Thommasi in constructing a regulator for the Jablochkoff candles, by which the point of luminosity is kept at a uniform intensity.

UNITED TELEPHONE COMPANY.—This company announces a dividend of 6 per cent. per annum for the year ending 30th April last. The directors resolved to recommend to the shareholders at the annual meeting, to be held on the 24th inst., the issue to the shareholders, *pro rata* to their respective holdings, of the remaining 20,000 £5 shares at £2 per share premium.

THE DYNAMICABLES.—On Friday, July 6, this social society met to dine at the Fisheries Exhibition, under the presidency of Professor W. G. Adams. There was a comparatively large gathering, and after dinner the exhibition was visited, not only by the members, but by lady and other friends who had been invited. Some grumbling was heard at the arrangement which necessitated the leaving of ladies to their own resources for a couple of hours or so while the members were at dinner. Is there an insuperable difficulty in such cases in inviting ladies to dinner?

ELECTRIC LIGHTING AT THE WEST END.—The Marquis of Salisbury's town residence, Arlington-street, is now lighted by Swan lamps. A 16 horse-power Otto gas engine has been fixed in the courtyard and drives a Siemens single current shunt wound dynamo machine, which produces sufficient current to maintain upwards of 300 Swan 100 volts 20 candle-power lamps. These have been arranged in parallel circuit on the present beautiful gilt candelabra, with the best possible effect. The work has been carried out by Mr. Shillito, the marquis's engineer, by whom the whole of the fittings have been designed.

ELECTRIC ALARUMS.—The *Novoe Vremya* states:—"A Russian inventor, the State Councillor of Kratkow, has just proposed to the Ministry of Finances the introduction of an apparatus which he calls the 'Electrical Guardian.' These instruments consist of electric conductors, connecting the safes of strong rooms to a strong alarm bell. The slightest interference with the safe puts the apparatus in motion and gives the alarm. By a recent improvement of the inventor this apparatus is made to sound the alarm in case the cashier forget to lock the safe. The price of this apparatus, including erection, fittings, &c., does not exceed 500 roubles (£50).

PARLIAMENT AND THE ELECTRIC LIGHTING ACT.—Commenting on the decision of the House permitting petitions to be lodged in Committee against provisional orders, *The Times* says:—"The enlargement of the reference to the Select Committee on which the House of Commons yesterday insisted is justified, perhaps, by the exceptional circumstances of the case, since where all is so novel and uncertain it is as well not to be tied down too strictly by technical rules adapted to more ordinary conditions. But it undoubtedly establishes a precedent which may be dangerous if loosely applied, and though it may justify itself in the end, it is only too likely to retard for a time the progress of public electric lighting."

ELECTRIC RESISTANCE OF PSILOMELANE.—Meyer's experiments with thin plates of psilomelane agree so far with those of Braun in demonstrating that such plates exhibit a remarkable unipolar conductivity. He shows that the resistance in one direction to that in the second direction is dependent on the intensity of the current, for on changing the

Digitized by Google

latter the position of unipolar conductivity can be reversed. In other experiments with different plates it was found that the resistance was independent of the direction, continuance, and intensity of the current. No explanation is given as to the causes of the difference of action in the specimens. Meyer's experiments with pyrites and galena accord with those of Dupel, but not with those of Braun.

The Eastern Telegraph Company.—This company is now issuing 4 per cent. Mortgage Debenture stock, to the amount of £500,000, at £95 per £100 stock. From the advertisement which appeared in our last it will be seen that the principal objects of this issue are the redemption of terminable debentures falling due next October, and to pay for the Trieste-Corfu cable. The shares of the company are now at a premium, and during the past three years its dividends and bonuses have been at the rate of 5½ and 6 per cent. The reserve fund also amounts to £569,828, of which £328,574 is invested in securities. Applications for shares of the present issue should be made to Messrs. Glyn, Mills, Currie, and Co., 67, Lombard-street, London, accompanied by a deposit of 5 per cent. per share applied for.

The Director-General of Russian Telegraphs at Odessa.—Major-General de Bezack, the Russian Minister of Telegraphs, and successor of the late General von Lüders, visited Odessa on July 3, on a tour of inspection. His Excellency was received on board the steamer from Nicolaieff by the departmental authorities of the city and district of Odessa and Cherson, and by Messrs. F. H. Billows and J. Heyl, representing respectively the Indo-European and Eastern Black Sea Cable Companies. His Excellency, with a numerous suite, next day made a minute and lengthened inspection of the stations and traffic routine of the two English companies, and expressed himself highly satisfied with all he saw. The Director-General goes from Odessa southwards, *viâ* Kieff, in order to be present at the forthcoming Electrical Exhibition at Vienna.

Zinc Coating for Iron.—Attention has recently again been drawn (says the *Scientific American*) to MM. Neugean and Delaite's process of protecting iron surfaces against rust. A very fine powder of metallic zinc is mixed with oil and a siccative, and applied to the iron by means of an ordinary brush. In many cases one coat is sufficient. Two coats are at any rate guaranteed to secure a protection against the corrosive action of the atmosphere as well as of sea water. The zinc coating gives the iron a steel gray appearance, and it does not interfere with subsequent painting. MM. Neugean and Delaite received a diploma at the Paris Electric Exhibition of 1881, and now recommend their process for iron structures, bridges, lamp posts, &c., and also for iron ships. If this process really affords the protection it claims, nothing need be said in recommendation of it, since it can hardly be surpassed in simplicity and cheapness, and is capable of application in cases where galvanising, the Bower-Barff and similar processes, would hardly be practicable. A good mixture, of which only the necessary quantity ought to be prepared, consists of eight parts by weight of zinc, 71 of oil, and two of a siccative.

Electrical Torpedoes in the Potomac.—Two torpedoes have been taken out of the Potomac river, at Washington, from the channel near the mouth of the branch, by the boatman on the large Government dredge which has been dredging the channel. The first one was found about six weeks ago, the other on the 16th. The first was taken to the ordnance machine shop, emptied of the powder, cleaned and examined. The second is made of light boiler iron, in the shape of a cylinder, about three and a half feet in diameter and about the same in length. It contained about two barrels of coarse gunpowder, which was fortunately wet at the time it was scooped in. The copper wire attachments to be connected with an electrical battery to explode it are still intact. There are two small holes in the iron, caused by rust. After taking the first one out and discovering that it was full of wet powder, the workmen were very particular about how they handled the second until they were satisfied that the powder in it was also wet. Had either of them been made of copper they would have been thoroughly dry inside, and as the scoop made a large indentation in the sides of them, they might have exploded and blown up the vessel and all on board.—*Electrical World.*

Exhibition of Electric Lighting.—At a meeting of the Mining Institute of Scotland, which was held in the Christian Institute, Bothwell-street, on Thursday, July 5, Mr. James M'Raith in the chair, the discussion on Mr. Connell's paper was resumed. The subject was "Spontaneous Combustion of Coal in Ships." Having accepted an invitation from the Edison Electric Light Company, the members of the institute on the conclusion of their discussion visited the office in West Nile-street, and were shown the Edison lamps in use. The members were afterwards entertained to an exhibition of the different systems of electric lighting and apparatus by Messrs. Norman and Son, engineers, Argyll-street. The company was received by Mr. Musgrove, the senior partner of the firm, who introduced Mr. M'Whirter, the manager. The latter gentleman explained the various processes and different systems of electric lighting. He first gave an exhibition of the working of the Crabbe lamp, which he said is a modification of the Crompton light. The latest improvement on the Crompton lamp next engaged the attention of the company. Mr. M'Whirter explained that whereas this lamp at first only burned for about five hours, it now, by altering the arrangement, burned for 12 or 13 hours without a change of carbon.

Sixpenny Telegrams.—On Thursday, 5th inst., Mr. Fawcett, in reply to Mr. Puleston, said that the Government had decided not to come to any decision with regard to the particular form of introducing the sixpenny telegram until next Session. There would be then no objection to give, as far as possible, the financial results that might be anticipated from any of the three plans mentioned in the Treasury minute. In answer to Mr. Alderman Lawrence, Mr. Fawcett said it was, no doubt, the case that, under Schemes 1 and 2, it would be possible, under certain circumstances, that a higher charge would be made for telegrams of twenty words than at present, but he could not agree with his hon. friend that there would be few telegrams for sixpence. On the contrary, he thought that under either of these schemes a great number would be sent. As he stated the other day, no particular scheme would be adopted till next Session. If any change whatever was adopted, with regard either to free addresses or what would render it possible to charge more than 1s. for twenty words, it would be necessary to introduce a Bill.—Mr. Alderman Lawrence gave notice that he would move "That any scheme for reducing the minimum charge for Post Office telegrams to sixpence should recognise the fact that much longer addresses are required by artisans and small traders than by merchants and bankers."

Dry Batteries as Accumulators.—Herren J. Elster and H. Geitel have recently been making experiments in this direction. Between the conductors of a Holtz machine they interposed a Zamboni dry battery consisting of 11,000 elements of one square centimetre in section. The copper pole touched the positive conductor of the machine, the negative conductor being in connection with the other pole. After 10

Digitized by Google

minutes' interval the E.M.F. of the battery had so far increased that a spark was produced between its poles when they were at one millimetre distance. The battery, polarised in this way, caused continuous action in a small Geissler tube. This led Messrs. Elster and Geitel to endeavour to construct a secondary battery with one metal only, taking as their model the Planté battery. On each face of a leaf of lead paper they pasted a leaf of tissue paper impregnated with a solution of silicate of potash, having a little oxide of lead added to it. They divided the whole up into little discs of one square centimetre, which they piled the one on the other to the number of 7,000. Treated like the Zamboni battery, this latter gave slightly greater results. If, in place of forming the battery electrically, it is constructed with binoxide of lead ready formed, the effects obtained are less strong. The experimenters consider these dry batteries as very effective for showing to a large audience the principle upon which accumulators work.

The Chelsea Vestry and Electric Lighting.—At the last week's meeting of the Metropolitan Board of Works Mr. R. Cox introduced a deputation from the vestry of Chelsea, who presented a memorial, calling attention to some of the allegations in the Board's petition against the Electric Lighting Provisional Orders Bill for confirming provisional orders relating to Chelsea and Greenwich, and asking the Board to reconsider the question whether it is advisable to follow up the said allegations. The memorialists stated that they had learned with much surprise and regret that this Board had presented a petition against the Electric Lighting Provisional Orders Confirmation Bill in so far as it affected the parish of Chelsea. They viewed with grave concern this step taken by the Board inasmuch as if persisted in its probable effect would be to prevent the passing during the present Session of the said Bill, and so to defer the introduction of electric lighting into the parish of Chelsea for at least two years. The memorialists were of opinion that the establishment and exercise of a divided responsibility and authority had generally a mischievous tendency, and were productive of unseemly litigation and conflict between public bodies. They therefore prayed that the Board would see fit either to withdraw the said petition, or so to amend the same that all reference to the parish of Chelsea might be excluded therefrom. After some discussion the memorial was referred to the Board's Parliamentary Committee.

Preparation of Carbons for Electric Lighting.—M. Jacquelain has endeavoured to prepare carbon of like density and conducting power to gas-carbon and without its impurities. He removes impurities by three processes: (1) Treatment with dry chlorine at a red heat for thirty hours to remove silica, metallic oxides, and hydrogen. (2) Treatment with fused potash or soda. The alkali must not be too strong nor the temperature too high; Na_2O, with three equivalents of water answers well. An immersion of three hours is generally sufficient, after which the carbon is washed with water, then with dilute hydrochloric acid, and again with water. (3) Immersion in hydrofluoric acid diluted with twice its weight of water from twenty-four to forty-eight hours at a temperature of 15° to 25°. The gas carbon may be submitted to either of these processes after being cut into pencils. To restore the carbons to their original density they are carbonised by being strongly heated for a few hours in the vapour of some heavy hydrocarbon. Pure graphitoid carbon may be prepared directly by passing the vapour of some heavy hydrocarbon through a fire-clay tube raised to a temperature of 1,000° to 1,200° C. Hydrocarbons with high boiling points answer best, and gas tar is the most suitable for use on a commercial scale. The steadiness of the light and durability of the carbons are in direct proportion to their hardness, density, and purity. The best results in experiments have been obtained with Siberian graphite (sp. gr. 2·3, gas carbon being 1·9) purified by treatment with hydrofluoric acid, by which process the percentage of ash was reduced from 8·674 and 5·184 to 0·767 and 0·900.

Electric Lighting Provisional Order Bills.—In the discussion in the House of Commons on Thursday, the 5th inst., relating to this subject, Mr. Chamberlain stated that he had not understood that the fact of the substitution of a hybrid committee for a Select Committee was to have any effect upon the *locus standi* of petitioners. The Electric Lighting Act made the vestry the local authority, and the vestry of St. James's had assented to the order applied for by the Edison Company. The Telegraph Construction Company had now come forward with a proposal to light the district at a maximum price 40 per cent. below the maximum offered by the Edison Company. That was an *ex parte* statement, and if an order were granted upon it what was there to prevent another company from coming forward and asking them to go all through the matter again because it offered a maximum 5 per cent. cheaper than that of the Telegraph Construction Company. In this way they might go on as long as there were any promoters, speculative or otherwise, offering to do the work more cheaply. It must be remembered that in fixing a maximum a margin was allowed above the price at which the competition of gas companies would cause the light to be supplied, and therefore it did not follow that the public would obtain an advantage from a lower maximum. It seemed to be assumed that the inhabitants were to be bound to a monopoly for twenty-one years, but all that was done by an order was to give a company power to take up the streets and lay down wires, and the companies were distinctly informed that they were not granted a monopoly. The Telegraph Construction Company could, therefore, if it could show that it was able to supply light more cheaply, apply for and obtain a competing order. When the inhabitants of a district were represented by their local authorities it was not usual to allow the inhabitants themselves a *locus standi*, and in this case the vestry of St. James's had been heard. After some discussion, however, Mr. Chamberlain yielded to the opinion of the House that petitions against the Bill be allowed and referred to a Select Committee.

The Telephone and Induction.—The experiments of Herz and Rysselberghe prove that telephonic communication is possible over lines of considerable length, though the practical solution is not yet attained, due probably to the unsuitability of the instruments hitherto used. It is found, for instance, that though the thin steel diaphragm of the American type of telephone speaks with clearer articulation on short lines, that on longer ones the thicker plate of the Siemens form gives far better results. Dr. V. Wietlisbach theoretically determined the maximum distance over which such communication is possible, considering the limiting effect of the nature of the conductor in the first place, and, secondly, the interference of neighbouring lines. On the first point the rate of transmission of electric waves is a function of the resistance and electrostatic capacity of the circuit, the increase in the product of these two quantities corresponding with diminution in amplitude and velocity of the wave. This retardation is also a function of the rate of vibration of the sound, so that if the assumption is made that each sound must have a duration of at least $\frac{1}{10}$ second, and a retardation of not more than $\frac{1}{100}$ second between the highest and lowest tones be allowed, the limiting distance for an underground

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA
Digitized by Google

cable similar to the type adopted by the German Government would be 1,300 kilometres (800 statute miles), about the distance between Berlin and Paris or Vienna. As the capacity on overhead lines is, however, considerably less, the limiting distance in their case would be much greater. On the second point distinction must be made between the disturbance resulting from electrostatic and electro-dynamic induction; the first can be prevented by enclosing the insulated conductor in a metallic sheath, as has already been done. The second is, however, not easily prevented. It can theoretically be overcome in certain cases by increasing the resistance of the receiving instrument to a value considerably exceeding that of the lines, but as this also reduces the sensitiveness of the sending instrument, and the dimensions would so rapidly increase with the length of the line, this method is not practicable. On short lines, Professor Hughes's induction balance might be applied, but this again exceeds the limits of practicability for more than two or three parallel lines. The only real way out of the difficulty is the use of a metallic return circuit entwined with the original conductor, so that the induced currents are balanced on the two parts of the circuit. The especial difficulty in any other solution of this problem is that the induced currents are more powerful than those excited by the microphonic sender; hence the numerous proposals for increasing the action of the latter.

International Electrical Exhibition, Vienna, 1883.—For some weeks the preparations for the International Electrical Exhibition have conjured a gay and stirring life in the vast rooms of the Rotunda, at other times so quiet, which must interest every visitor on account of the great contrast with the intense quietness of the surrounding greens of the Prater. From early morn till late at night echo through the vast exhibition rooms the sounds of different works; here the monotonous song of the pile drivers, there the planing, sawing, and boring of the lumberers, yonder the creaking of the carts, conveying building materials, or the jarring of the wheel-barrows, removing the clay, and everywhere the knocking and hammering of electricians, drawing on high ladders a whole net of conducting wires through all rooms of the Rotunda, or clearing the way for them underground. Many of these industrious men will not even have the satisfaction of seeing the results of their eager labour duly admired, for many and not the least of these works will entirely withdraw from sight, as they are laid under the floor, or hidden somewhere else. Thus particularly the part of the mason and building works, which we will especially speak about to-day. While those works of the theatre, the two restaurants, the interiors, the different pavilions, the telephone rooms, and the reading hall are being surveyed by the architect, Alexander Décsey, who has made the designs for these objects, the foundations of the steam engines and dynamo machines, and its transmissions, as well as the disposition, foundation, and setting of the boilers, are being executed according to the designs of the engineer, Professor Tosef Pechan, and under the management of the engineer, Wilhelm Fletinsky, and carried out by the contractors, Messrs. Frauenfeld and Berghof. Adjacent to the large chimney mentioned in former reports, for which 700 cubic metres of brick masonry have been employed, will be the boiler shed, with two wings, built in right angles of 64 metres in length each. The latter will be connected with the machine hall by covered passages, and will cover a space of 2,250 square metres. The whole earth-work in the galleries and the boiler-shed amounts to about 2,000 cubic metres, and in masonry work fall out for the boiler-house and flues 250 cubic metres, for the foundations of 14 stationary boilers 150 cubic metres, for the foundations of 22 portable steam motors 150 cubic metres, for the foundations of stationary engines and 8 gas engines with round 1,200 horse-power for driving the dynamo machines, 1,200 cubic metres for the foundations of the transmissions, dynamo machines, and different other arrangements about 900 cubic metres. All in all, therefore, about 3,350 cubic metres of masonry, the entire completion of which will take place within a few days. In the meantime begin the consignments of exhibits from all parts of the globe, and the places will soon be occupied by boilers, machines, and other objects.—*Communicated.*

Mr. Edison's Opinion of Electricity as a Motor.—Mr. Edison was questioned recently as to the feasibility of running trains by electricity on the regular railroads. The *Electrical World* quotes Mr. Edison's remarks, but does not give its authority:—" The manner in which it is proposed to operate the railroads by electricity," he said, "is by means of a central rail laid between the existing tracks, for which old and worn-out rails might be used, this rail acting as one pole and the other two forming the other. The power would be transmitted by a central engine with the use of powerful dynamos, and the electricity would thus be supplied to the rail, from which it would be taken up by the motor attached to a train where there are two or more cars attached. In the case of street surface the motor could be carried underneath, and would not necessitate an extra carriage for a motor engine. The whole operation would be similar to the endless rope by which cars are drawn along in Chicago and other cities. The method of stopping would be by means of a 'clutch,' whereby the electric power would be thrown out of gear so far as it operates on the drawing or driving power of the motor, while at the same time the current would still be kept operating on the motor so that a start could be effected at a minimum loss of power, similar to the shifting of a belt on a shafting." The advantage he claims for the new invention is that it will effect a saving of 33 per cent. in the amount paid for coal under the present system of steam locomotives. There would also be a slight saving in the matter of the wear and tear of the two different styles of engines or motors. "For the present," continued Mr. Edison, "I do not think that electricity will be generally adopted for heavy freight trains or for passenger trains over long distances, but for street cars, elevated railroads, and other short lines it will be found invaluable. Already we have applications for the use of our patents from Coney Island, Long Branch, Fairmount Park, Saratoga, and from the elevated railroads in New York. In the case of the latter it will effect not only a saving of 33 per cent. in the matter of coal, but it will also do away with one man on each engine, and further save the annoyance now experienced in the matter of the shower of sparks and the smell of sulphur which is so objectionable." The exact form the motor attached to a train would take he could not, he said, at present give, but he believed it would take one of the shapes of Mr. Field's patents. The matter of snow would be no impediment to the transmission of power, as a sort of a cow-catcher had been devised that would so come in contact with the central rail through which it would be transmitted that it would at all times and in the severest storm be entirely cleared off. Any rate of speed could be obtained, according to the power used at the central depots. When asked if he thought steam as a motive power would be eventually superseded by electricity, Mr. Edison said that he had no doubt such would be the case, but not for some years to come. Steam, he said, is now and will be essential to the generation of electricity, but he believed that means sooner or later will be found to obtain

Digitized by Google

electricity from the earth without the use of any machinery whatever.

The Metal Trades Exhibition.—We briefly mentioned in our last issue that in this exhibition there would be found one or two exhibits of a distinctly electrical nature. Opposite the main entrance is the exhibit of Messrs. Felten and Guilleaume, whose agents in England are Messrs W. F. Dennis and Co. The firm owns two works, viz., the hemp-spinning mill "Rosenthal," in Cologne, and the wire, wire-rope, and telegraph-cable manufactory "Carlswerk," in Mulheim-on-the-Rhine. The Cologne works produce thread, twine, and hemp ropes at the rate of 2,500 tons per annum; they employ about 600 hands and engines of 500 horse-power. The Mulheim works embrace the wire-drawing mills, the very extensive galvanising shops, the wire ropery and the telegraph cable manufactory. The annual production amounts to about 30,000 tons, 1,200 hands are employed and engines of 750 horse-power. The value of the annual production of both works comes up to about £1,000,000 sterling. This firm was the first in Germany to manufacture galvanised telegraph wire, and in 1852 they made the first delivery of such wire to the then existing Prussian Telegraph Department. The year following they were the first on the Continent of Europe to commence manufacturing telegraph cables, and ever since they have been closely connected with the development of underground telegraphs, taking a deep interest and a very active part in the improvements of underground cables for that purpose. In 1875 Messrs. Felten and Guilleaume were called upon by the Prussian Government to make the first extensive underground telegraph line for a trial, viz., from Berlin to Halle, a distance of 170 kilometres. When this trial line had given every satisfaction, the postal authorities gave orders to proceed with the network of underground telegraph lines proposed for the whole of the German Empire. This system of underground lines, embracing about, 5,100 kilometres of cable, and altogether 38,000 kilometres of insulated conductors, has been completed, and this firm has manufactured and laid down the larger part of the above-mentioned system. They have supplied the galvanised sheathing wire for many of the large submarine cables which have been laid down for some years. It may here be mentioned that last year the manufacture of galvanised wire for sheathing cables as well as for overhead lines reached the extent of 15,000 tons, and that this year their supply of wire for the said purposes will exceed that figure. The manufactures which have no connection with electricity may be left unnoticed for the present, and we proceed to offer a few remarks with reference to the cables and wires, which are exhibited in a very handsome glass case. The middle compartment contains samples of wire ropes for aerial tramways, lightning conductors, ships' rigging, and steel hawsers; the right-hand one hemp rope, twine, &c.; the left-hand cables for field telegraphs and torpedoes, with various coverings. The electric conductor of nearly all the cables is composed of seven fine copper wires, made of the purest copper in order to keep the electrical resistance as low as possible. With the exception of a few special cases, where india rubber has been taken for some reason, the conducting wire is insulated by gutta percha, which surrounds the wire in several layers, and of a thickness to meet the requirements, as the case may be. The gutta percha is most carefully cleaned of all its impurities, all the air has been scrupulously expelled to prevent the formation of air-bubbles, and no trouble has been spared to obtain as dense and uniform a material as possible, so as to insure a perfect insulation of the wire. The hemp which is wrapped round the insulated wire, and which is to protect the latter against being injured by the sheathing wires, has been dipped in tar specially prepared for preventing the hemp from rotting without doing the gutta percha any injury. The size of the material and the material itself for the sheathing have been selected with due regard to the purpose the cable is to serve and the work it is expected to do. The final coating of compound which is to give the cable an air-tight jacket has not been put on some of the cables for the purpose of allowing the sheathing wire to be exposed to view. Field-telegraph and torpedo cables must be as light as possible, and they should also be very pliable, and yet able to resist a heavy breaking strain. For these reasons steel wire is used for sheathing such cables. To make them more pliable, strands of thin steel wire have been employed instead of solid sheathing wires; and to prevent the formation of kinks, which in laying out the cable so often cause the conductor to snap, one-half of the strands are laid with a right turn, the other strands being laid in the opposite direction. This arrangement of alternate laid sheathing strands is also a good safeguard against the cable becoming severed when attached to a swinging buoy. The same considerations have ruled the construction of the anchor-ropes for torpedoes and mines, of which a few samples are exhibited with the cables. The insulated and covered wires in the left hand compartment are for different purposes; some are insulated with gutta percha, others are not; some are covered with cotton yarn, others with prepared tape. For conducting powerful induced currents for electric lighting and other purposes the copper conductor is formed of a number of thin wires properly stranded, the whole of a metallic section proportionate to the strength of a current and to the distance of the place of application (for instance the lamp) from the source of electricity (the dynamo). This copper conductor is supplied with either a single or a double, or even a three-fold wrapping of prepared tape, which resists most effectually the destructive power of an induced current. In the centre of their stand is a fine pyramid rising to 15ft., composed of various qualities of wire, viz., galvanised patent steel wire, galvanised oiled steel, iron fencing wire, coppered and galvanised spring wire, telegraph wire, tinned wire, and annealed weaving wire. On the left a rather smaller pyramid of galvanised wire rope, &c. On the right are two smaller show cases containing some good samples of electric light wire, telephone wires, patent steel music wire (which they have lately commenced to manufacture), and submarine cables. At each end there is a fine collection of electric light conductors, also lead covered cables and telephone leading in wires. They also show a coil of patent cast-steel galvanised mooring rope for torpedoes, the strands alternately twisted to the right and left hand, composed of 6 strands, each 7 wires, and main hemp core; also a coil of patent cast-steel wire rope, the strands and rope both being twisted in the same direction, and composed of 6 strands, each 7 wires, and a main hemp core. The firm consider their patent cast-steel wire to be the best for telephone purposes, on account of its high breaking strain and great tenacity and elasticity, which are all very valuable qualities for telephone lines, where the supports are mostly placed at considerable distances apart. The patent cast-steel wire is made to any breaking strain up to 120 tons per square inch. With this patent wire the margin of elasticity very closely approaches the breaking strain, and thereby this wire is enabled to store the tension caused by the contraction in cold weather, and to yield it again without suffering an elongation when warmer weather sets in. These and other specimens make this exhibit worthy of attention.

CURRENT ENERGY.—V.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 150.)

When we apply Ohm's principle of the constancy of the resistance co-efficient in the most general manner possible to bodies which conduct differently in different directions, a remarkable consequence is the establishment of the possibility of existence of a *rotatory* resistance co-efficient, or rather of three co-efficients which specify a definite axis of rotation. Thus, in order to express without hypothesis the relations between E.M.F. and current at any point, we require no less than nine co-efficients of resistance, or an equal number of conductivity, viz., three direct and six transverse; a direct co-efficient referring to the current produced in a certain direction by an E.M.F. acting in that direction, and a pair of transverse co-efficients to express the component current in the plane perpendicular to the E.M.F. Taking x, y, z for any three rectangular axes of reference through the point considered, let an E.M.F. of strength X along x produce currents k_{11} X, k_{21} X, k_{31} X along x, y, and z respectively, these being the components of the actual current, and employ a similar notation for E.M.F.'s acting along y and z. Then, if any E.M.F. of strength E, whose components are X, Y, Z, produce a current C, whose components are u, v, w, we have the equations of conductivity,

$$u = k_{11}\,X + k_{12}\,Y + k_{13}\,Z;$$
$$v = k_{21}\,X + k_{22}\,Y + k_{23}\,Z;$$
$$w = k_{31}\,X + k_{32}\,Y + k_{33}\,Z;$$

where the k's are the nine co-efficients of conductivity, k_{11}, k_{22}, and k_{33} being direct, and the rest transverse. We have, of course, an exactly similar set of equations of resistance, expressing the E.M.F. in terms of the current, thus,

$$X = r_{11}\,u + r_{12}\,v + r_{13}\,w;$$
$$Y = r_{21}\,u + r_{22}\,v + r_{23}\,w;$$
$$Z = r_{31}\,u + r_{32}\,v + r_{33}\,w;$$

where the values of the r's, the co-efficients of resistance, may be put in terms of the k's by solving the former equations for X, Y, Z.

Now, these equations are of the same form as those concerned in the transformation of a sphere into an ellipsoid, exemplified in the theory of strains, and we may thus interpret them. Let the E.M.F. at the point considered be of constant strength, but variable in direction. Representing it by a straight line drawn from the point, the extremity of this line of E.M.F. will obviously travel over the surface of a sphere when we vary its direction. At the same time, the corresponding current will vary both in direction and strength, and if we represent it also by a straight line drawn from the centre of the sphere, then as the extremity of the line of E.M.F. travels over the spherical surface, that of the line of current will travel over the surface of an ellipsoid.

There is, therefore, in general, corresponding to an E.M.F. of constant strength, but variable direction, a direction of maximum current, one of minimum current, and a third minimax, corresponding to the three principal axes of the ellipsoid. Two axes may be equal, or all three, in which last case the ellipsoid becomes a sphere.

Similarly, let it be the current that is kept of constant strength whilst its direction varies, and represented by a straight line of constant length, whose extremity, therefore, travels over a spherical surface. Now it is the E.M.F. required to produce the current which varies in strength in different directions, and as the line of current travels over the spherical surface, that of E.M.F. travels over the surface of an ellipsoid. But this second ellipsoid has not in the general case its principal axes in the same direction as those of the first. For this to be the case there must be a certain symmetrical relation, which may be thus expressed. E_1 and E_2 being any two E.M.F.'s, and C_1 and C_2 the currents they produce, then we must have $\overline{E_1C_2} = \overline{E_2C_1}$, or in terms of components

$$X_1u_2 + Y_1v_2 + Z_1w_2 = X_2u_1 + Y_2v_1 + Z_2w_1.$$

The interpretation of $\overline{E_1C_2} = \overline{E_2C_1}$ is that an E.M.F. acting in any direction produces the same component current in any second direction, as the same E.M.F. acting in the second direction does in the first.

In a system of connected linear conductors the corresponding property is that the current produced in a branch R_2 by an E.M.F. in another branch R_1 equals the current in R_1 due to the same E.M.F. in R_2, with similarity of direction. That is, choosing the directions of E in R_1 and of C in R_2 as positive, when E is transferred to R_2, and acts in the assumed positive direction, C will be also in the assumed positive direction in R_1. This reciprocal property is necessary in a system of linear conductors; but there is nothing to prove that the corresponding law $\overline{E_1C_2} = \overline{E_2C_1}$ is necessary in a non-isotropic conductor. But, supposing it to exist, it follows that the transverse co-efficients are equal in three pairs; thus, $k_{12} = k_{21}$, &c., and $r_{12} = r_{21}$, &c. The principal axes of the two ellipsoids above mentioned are now coincident in direction, and if we choose them for our axes of reference (x y z), we reduce the general equations to the simpler forms

$u = k_1X$, $v = k_2Y$, $w = k_3Z$; and $X = r_1u$, $Y = r_2v$, $Z = r_3w$,

where the k's are the principal conductivities, and the r's the principal resistances, viz., along the common axes—and now, which was not the case before, the r's are the reciprocals of the k's.

From these equations we see at once that there are three lines of directional identity of the current and the E.M.F., viz., the three mutually perpendicular principal axes for which the current is maximum, minimum, or minimax, with an E.M.F. of variable direction but constant strength. In any other direction there is not coincidence, thus l, m, n, being the direction cosines of the E.M.F., those of the current are lk_1/k, mk_1/k, nk_1/k, where $k = \sqrt{l^2k_1^2 + m^2k_2^2 + n^2k_3^2}$; and the strength of current is $C = kE$.

If we describe an ellipsoid whose axes are along the principal axes, but of lengths proportional to the square roots of the principal resistances, and let the radius vector from the centre to any point of the surface represent the E.M.F. in magnitude and direction, the corresponding current will be parallel to the normal to the surface at the point, therefore along the perpendicular from the centre upon the tangent plane, and its strength will vary inversely as the length of the perpendicular. Similarly, with an ellipsoid whose axes are of lengths proportional to the square roots of the conductivities, the radius vector representing the current, the E.M.F. will be inversely as the perpendicular on the tangent plane and in its direction.

When this symmetry does not exist (k_{12} not $= k_{21}$, &c.), we have rotation. Representing the E.M.F.'s by radii of a sphere, the lines of current trace out an ellipsoid, as before, but we no longer have the lines of directional identity of current and E.M.F. for the principal axes of the ellipsoid, for the ellipsoid is rotated as a whole about a definite axis, besides altering somewhat in shape to become another ellipsoid. Similarly with the sphere for current, the ellipsoid for E.M.F. is rotated, though not about the same axis, save in a special case. There may be still three lines of parallelism of current and E.M.F., though no longer mutually perpendicular, nor coincident with the principal axis; but also there may be only *one* such direction. And this last case is the special case of identity of rotation axis of resistance and conductivity, and exhibits the rotatory phenomenon in the simplest form. Let a conductor be isotropic in the first place, $E = RC$, or in terms of the components $X = Ru$, $Y = Rv$, $Z = Rw$, where R is the one resistance co-efficient, and introduce rotation upon the top of this. We may put $r_{11} = r_{22} = r_{33} = R$ in the general equations, and $r_{23} = -r_{32} = T_1$, $r_{31} = -r_{13} = T_2$, $r_{12} = -r_{21} = T_3$; which in a system of linear conductors would imply exact reversal of the reciprocal property. We now have

$$X = Ru + X_1, \qquad Y = Rv + Y_1, \qquad Z = Rw + Z_1$$

where $X_1 = T_3v - T_2w$, $Y_1 = T_1w - T_3u$, $Z_1 = T_2u - T_1v$. Multiplying X_1, Y_1, Z_1 first by u_1, v_1, w_1 respectively and adding, and then the same with T_1, T_2, T_3, we find

$$X_1\,u + Y_1\,v + Z_1\,w = 0 \text{ and } X_1\,T_1 + Y_1\,T_2 + Z_1\,T_3 = 0.$$

Hence the E.M.F., say E, whose components are X_1, Y_1, Z_1,

Digitized by Google

is perpendicular to the current C, and to a vector, say T, whose components are T_1, T_2, T_3. Also, if θ be the angle between T and C, we have $E_1 = TC \sin \theta$.

E is therefore resultant of two E.M.F.'s, one of strength RC in the direction of the current, the other of strength CT sin θ, perpendicular to C and to T. These three E.M.F.'s form the three sides of a right-angled triangle, of which E is the long side, whence, by the famous 47th, $E^2 = (RC)^2 + (TC \sin \theta)^2$, which gives $E = (R^2 + T^2 \sin^2 \theta)^{\frac{1}{2}} C$. Also, if ϕ be the angle between E and C, $\tan \phi = T/R$.

The one line of parallelism of current and E.M.F. is the axis of T, which indicates a definite direction in the body, independent of the directions of E or C. Put $\theta = 0$, and we have simply $E = RC$ when E acts along the axis of T. Next, let it act straight across the axis. Put $\theta = 90°$, then $E = (R^2 + T^2)^{\frac{1}{2}} C$, or the specific resistance is apparently increased from R to $(R^2 + T^2)^{\frac{1}{2}}$; but C and E are not parallel. C is still perpendicular to the axis, the same as E is, but is rotated through an angle ϕ, such that $\tan \phi = T/R$.

In the general case of E inclined at any angle to the rotation axis, the component of E along the axis produces current parallel to itself as ordinarily, and the component perpendicular to the axis current with resistance $(R^2 + T^2)^{\frac{1}{2}}$ and rotation ϕ. The sphere of E.M.F. becomes a prolate ellipsoid of revolution for the current, the long axis being parallel to T, and showing the one line (instead of three) of parallelism of C and E.

The necessity of nine co-efficients in the general case, and hence the possibility of existence of the rotatory effect, was maintained by Sir W. Thomson in 1854; Maxwell said there was reason to believe it did not exist in any known substance, but should be found, if anywhere, in magnets. Its actual existence was only demonstrated two or three years ago by Hall's discovery that it is developed in metals when placed in a powerful field of magnetic force.

Let there be a steady current in a straight isotropic wire, and for distinctness let it go from left to right in the plane of the paper, and be kept up by a battery. Now let the lines of force of a magnetic field pass straight through the paper, and therefore perpendicular to the current. Ignoring altogether the ordinary current of induction, examine what the effect of the rotatory resistance vector will be, assuming it to be parallel to the lines of force, say downwards through the paper. The current must be deflected in the plane of the paper, say from ⟶ ⟶ it tends to ↗ ↗. But this transverse current will alter the distribution of the surface charge, the upper half of the wire will receive a positive, and the lower a negative charge, independent of the original distribution. This will introduce a downward E.M.F. across the wire, tending to decrease the deflection. So long as any transverse current exists this opposing E.M.F. will increase; hence the final result is that it reaches such a value as to keep the current going straight from left to right as before the magnetic force was put on. Thus the deflection of the current can be but momentary; on its cessation the current goes on as before, but now under the influence of an impressed E.M.F. not in its direction, but from left to right with a downward slant, being the resultant of the original E.M.F. and of the transverse downward E.M.F., whose strength must be TC.

Two points of the wire, one above and the other below, which were originally at the same potential, are under the influence of the rotation made of different potentials, the upper being positive to the lower, and a current may be therefore taken off in a shunt wire between the two points. The difference of potential is, of course, greatly magnified by using a very thin sheet instead of a wire, and thus was rendered perceptible.

Before leaving Ohm's law solus and proceeding to conservation I cannot help unburdening myself of a conviction that has long been forcing itself on my mind with ever-increasing persistency. Ohm's law, although, singularly enough, its recognition was slow in the first place (for it is said that Ohm, who was a shy, retiring man, received the cold shoulder, and was shunted off into the obscurity of his garret with frozen grate), long ago became of immense practical importance, owing to the commercial value of the applications of electricity. But in the last few years its use has been multiplied enormously, through electric lights and one thing and another. In fact, for once it is used by the telegraph engineer it is used twenty times or more by an electric light man. Conceive, then, if you can, the electric light young man having to consult at every step volumes of tables and intricate formulæ to ascertain what current corresponded to a given E.M.F. in a given wire under given circumstances if its resistance were not, as it is, practically constant; if it were to vary, for instance, greatly with how long the current had been on, or with the E.M.F., or in innumerable other ways; for who shall say what might not have been? The electrician would be in a perpetual state of harassment, which would certainly tend to shorten his days though it lengthened his day's work. Now, is not this fitness of things as regards Ohm's law a powerful argument in favour of design? Can it be doubted that the constancy of R was providentially arranged to meet the requirements of man? I think this can only be contested by those wicked writers of dreary articles in monthly magazines whose pernicious stuff appears to be deliberately intended to undermine all our inherited faiths, and who seem determined to leave no place in the world for its own maker. At any rate, this argument in favour of a providence might be added (to keep it up to the times) as an appendix to the next edition of "Paley's Evidences," a work whose perusal I can cordially recommend to all who, having had their peace of mind destroyed by the scoffers, have a difficulty in getting to sleep at night. As for myself, I may add that such was its soothing and calming effect on the nerves that, like Ingoldsby's shirt that never was new, it was often begun but never got through.

NOTE ON MANCE'S BATTERY TEST.

BY E. RAYMOND BARKER.

This test consists in adjusting *a*, *b*, and R, until the deflection D of the galvanometer G remains constant, whether the key K be open or closed. Should R be adjusted to a resistance higher than that of B, D of G will be greater when K is closed than when open, but if R be given a lower resistance than that of B, the closing of K will lessen the D of G.

In the present example, let a Thomson's reflecting gal-

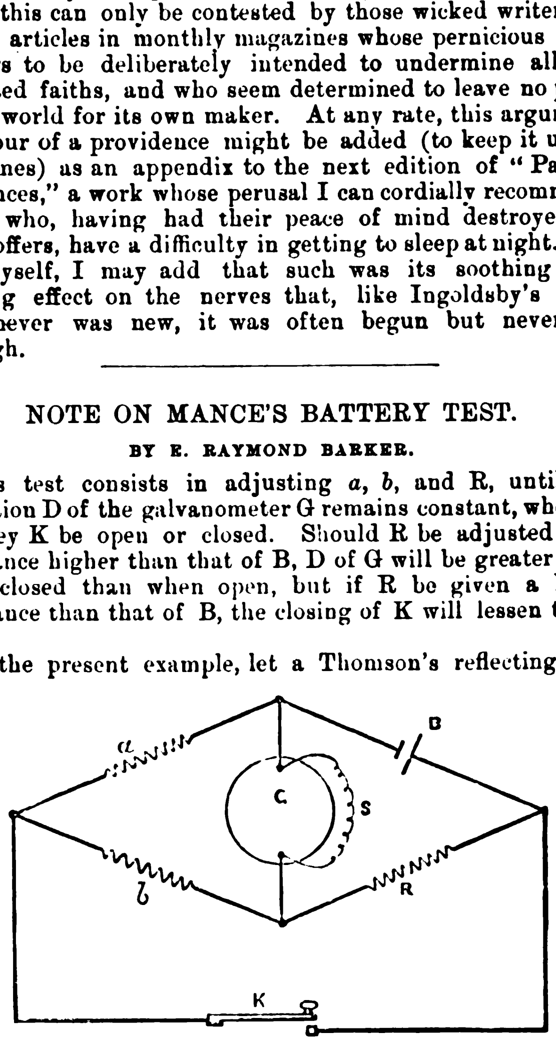

FIG. 1.

vanometer, G, be shunted with a short piece of "leading" wire, S, so that the resistance of G becomes practically *nil*, its sensitiveness being, however, sufficient to give an appreciable deflection. The theoretical arrangement of the test, as shown in Fig. 1, may be more clearly illustrated, as in Fig. 2.

Here we see B in circuit with R and the shunted galvanometer, the last-mentioned being still further shunted by the resistance $b + a$. With K *open*, however, the shunting action of $b + a$ upon G may be neglected, as G is already rendered of resistance *nil* by the short wire shunt S.

Then, with K *open*, the condition of things may be represented as in Fig. 3, but with K *closed*, the arrangement of the apparatus becomes as shown in Fig. 4.

Let us now inquire into the reason why, when equilibrium

Digitized by Google

is produced, D of G remains constant, whether K be open or closed.

Let us suppose that equilibrium has been produced, and, for simplicity's sake, let us give the value of 10 ohms to each of the four resistances—a, b, B, and R.

Let R′ represent the total resistance in circuit when K is open, as in Fig. 3.

Let R″ be total resistance in circuit when K is closed, as in Fig. 4.

Then

1. *With* K *open*:—$R' = B + R = 10 + 10 = 20$ ohms.

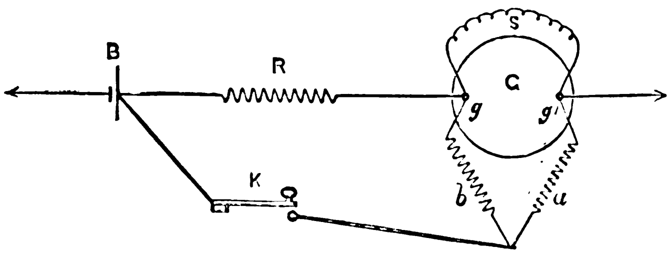

Fig. 2.

Under these conditions the whole of the battery current, say $\frac{3}{3}$ or three-thirds, traverses G, causing a D of, say, 80 divs.

2. *With* K *closed*:

$$R'' = B + \frac{\frac{Rb}{R+b} \times a}{\frac{Rb}{R+b} + a} = 10 + \frac{\frac{10 \times 10}{10 + 10} \times 10}{\frac{10 \times 10}{10 + 10} + 10}$$

$$= 10 + \frac{50}{15} = 13 \cdot 3 \text{ ohms.}$$

Here $R'' = 13 \cdot 3$ ohms, which is $\frac{2}{3}$ or *two-thirds* of 20 ohms, the value for R′.

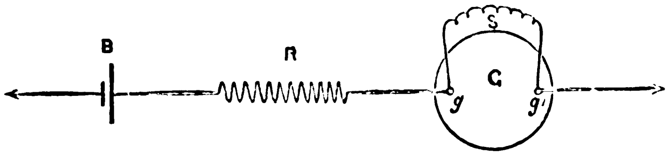

Fig. 3.

The total resistance in circuit being now *lessened* by *one third*, the conductivity of the circuit is therefore *increased* by *one third*, and were all the resistances a, b, and R to abut at one terminal g of G, the increased deflection due to a consequent increase in current would rise to about 80 + 40 = 120 divs. As, however, R and b only are connected to g, whilst a is carried on to terminal g', it is clear that the only current which will affect G will be that flowing through R and b, that is to say, through the joint resistance which we have seen $= \frac{10 \times 10}{10 + 10} = 5$ ohms.

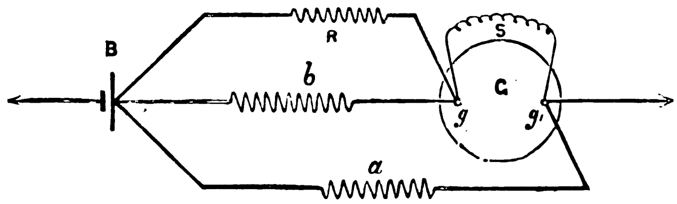

Fig. 4.

Now, this joint resistance in multiple arc of R and b is shunted by a of 10 ohms, the current in which latter in no way affects G, which is affected by that proportion only of current which traverses R and b.

Then, the system $\frac{Rb}{R+b}$ being of 5 ohms resistance, whilst the resistance of a is 10 ohms, it is clear that $\frac{2}{3}$ or *two-thirds* of the total current will traverse R and b, whilst $\frac{1}{3}$ will pass through a. Therefore, G is affected by only *two-thirds* of the passing current.

Thus it will be seen that the closing of the key K, besides *reducing* the total *resistance* from 20 to 13·3 ohms, that is to say, reducing R′ by *one-third*, and thereby *increasing* the total *current* by *one-third*, has also caused *one-third* of the increased current to be diverted from G. Therefore, in this instance, the increase brought about in the current by the closing of K in no way affects the D of G, for at the same time that the current becomes *increased* by *one-third*, *one-third* of the increased current is diverted from G, one operation exactly counterbalancing the other, so that the D of 80 divisions remains *constant whether* K *be open or closed*.

Having now ascertained the reason for the constancy of D of G when an equilibrium exists, that is to say when $a : b :: B : R$, let us now make an inquiry into the *rationale* of the fact that if R be of a higher resistance than B, D of G will be higher when K is open than when closed.

In the present example, let a, b, and B be each of a resistance of 10 ohms, whilst to R is given a resistance of 100 ohms. Under these conditions, we find that the closing of K considerably increases the D of G, thus showing that equilibrium has not been established, R being much higher in resistance than B.

Now, in the present instance, we have:—

1. *With* K *open*:

$$R' = B + R = 10 + 100 = 110 \text{ ohms.}$$

Under these conditions, let D of G be, say, 80 divisions.

2. *With* K *closed*:

$$R'' = B + \frac{\frac{Rb}{R+b} \times a}{\frac{Rb}{R+b} + a} = 10 + \frac{\frac{100 \times 10}{100 + 10} \times 10}{\frac{100 \times 10}{100 + 10} + 10}$$

$$= 10 + \frac{9 \cdot 09 \times 10}{9 \cdot 09 + 10} = 10 + 4 \cdot 76 = 14 \cdot 76 \text{ ohms.}$$

These figures show that the closing of K has increased the conductivity of the circuit $\frac{110}{14 \cdot 76}$ = nearly 7·452 times. This change would produce an increased deflection of $7 \cdot 452 \times 80 = 596 \cdot 16$ divisions, were the whole of the increased current allowed to influence G. However, the only current which affects G is that flowing through the system $\frac{Rb}{R+b}$ of 9·09 ohms.

Now, the conductivity of R shunted by b alone is seen to be increased $\frac{110}{19 \cdot 09} = 5 \cdot 7623$ times (for $B + \frac{Rb}{R+b} = 10 + 9 \cdot 09 = 19 \cdot 09$) so that the corresponding increase of current would produce an increased D of $80 \times 5 \cdot 7623$ = nearly 461 *divs.*, were it not that a of 10 ohms diverts nearly half the battery current from traversing G. If we suppose the current to consist of $a + \frac{Rb}{R+b} = 10 + 9 \cdot 09 = 19 \cdot 09$ parts, 10 parts may be said to traverse $\frac{Rb}{R+b}$, whilst 9·09 parts pass through a.

Now, it has been seen that 596·16 would have been the value for D of G had the whole of the increased current, after the closing of K, been allowed to traverse G. If this value be now divided by $\frac{19 \cdot 09}{9 \cdot 09}$, we obtain the value in divisions of scale for the actual D of G with K closed.

$$\frac{19 \cdot 09}{9 \cdot 09} = 2 \cdot 1001 \qquad \frac{596 \cdot 16}{2 \cdot 1001} = 283 \cdot 87 \text{ divisions.}$$

So, whilst with K open, we obtain a D of G of 80 divisions, with K closed D becomes increased to about 284 divs. This shows that, if R be greater than B, the galvanometer deflection will be larger when K is closed than when open. In like manner it might be shown that, were R adjusted to a lower resistance than B, the galvanometer deflection would be smaller when K was closed than when open.

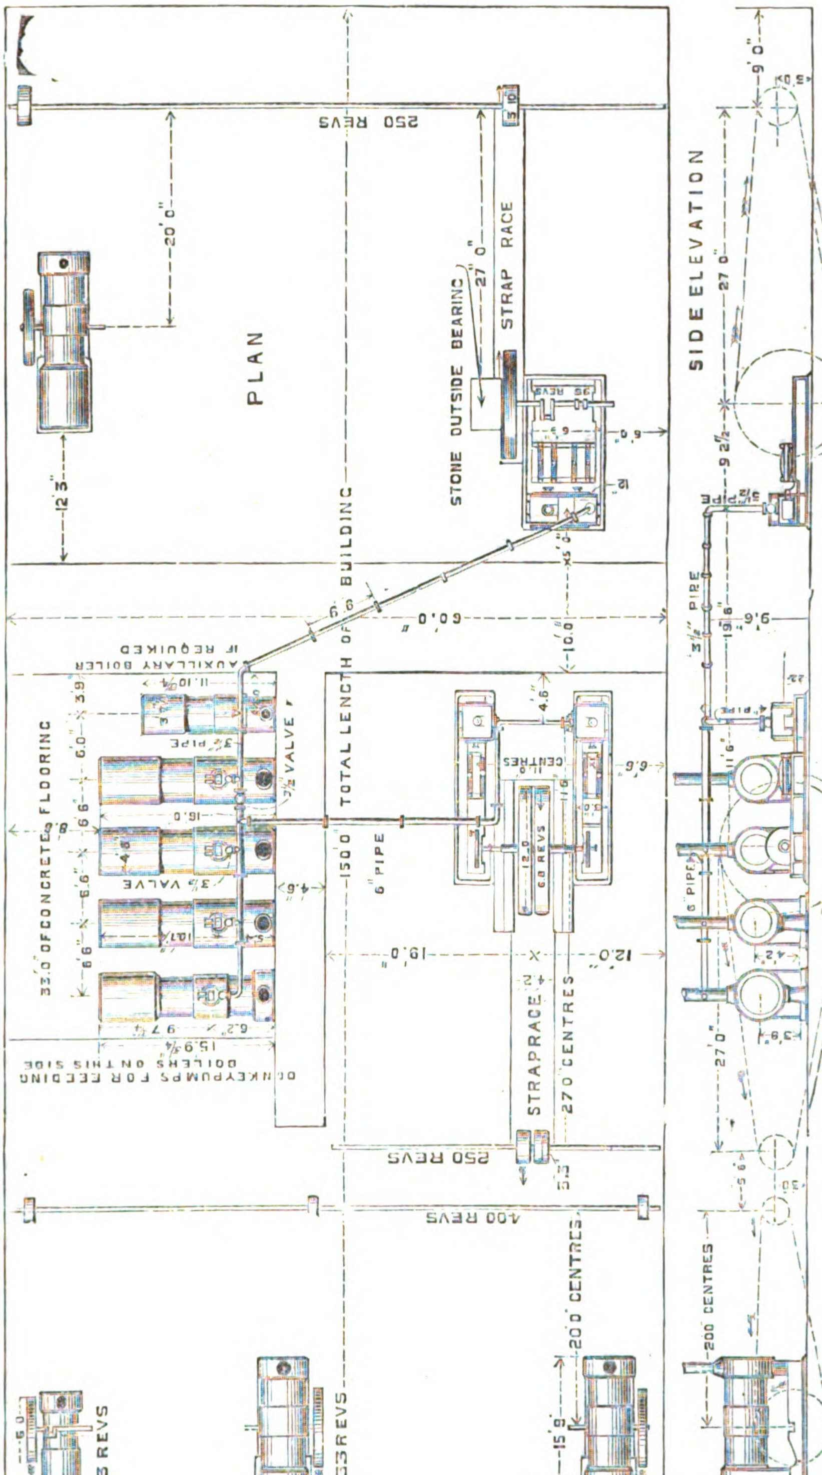
THE ELECTRIC LIGHTING INSTALLATION AT THE FISHERIES EXHIBITION.

In the history of electric lighting, the Great International Fisheries Exhibition of 1883 will be remarkable as having been lighted by the largest installation of its date. Larger displays of the electric light, as at the Crystal Palace Exhibition of 1882, have preceded it, but these consisted of a number of separate and distinct installations. For lighting the Fisheries Exhibition, however, a single installation has been arranged, and in one engine and machine room the whole of the electricity required throughout the exhibition buildings is generated and distributed by the several arc and incandescent lamp systems which belong to those who have



lent the dynamo-electric machines and other plant for the purpose.

In giving an account of a large installation like this, where about 1,100 or 1,200 indicated horse-power is employed, it is necessary to describe the different portions of

Digitized by Google

the plant separately, and in classifying these we shall take them in the following order: Engines and boilers, and shafting, &c., dynamo-electric machines, lamps, conductors &c.

Arrangement of Engines.

We give herewith a plan of the engine and machine room, from which it will be seen that six engines are employed, namely, two horizontal fixed engines, three semi-portable engines, and one portable engine. The four last-mentioned are complete with boiler, and the two fixed engines are supplied with steam by five boilers of the locomotive type. The whole of these engines and boilers have been provided and lent to the Commissioners by Messrs. Davey, Paxman, and Co., of Colchester, the well-known makers of engines for this and similar purposes. The engines may be thus enumerated. One pair of horizontal stationary engines working on one crankshaft with two fly-wheels, as shown in the centre of the plan, and of from 350 to 400 indicated horse-power. One compound horizontal engine of 250 indicated horse-power. Three semi-portable engines, each capable of indicating 100 horse-power, and one portable engine capable of indicating about 80 horse-power, or a total of 1,030 indicated horse-power when the engines are running at the speed and with the normal pressure intended by Messrs. Paxman and Co. Considerably more power than this will, however, probably be developed by employing rather higher pressures and speeds. On the eastern part of the engine and machine room are placed the compound fixed engine and one of the semi-portable engines, both working one line of shafting 5in. in diameter. This runs at 250 revolutions per minute, a rather high speed for such shafting, but one which reduces the necessary size of the pulleys upon it by which the dynamo machines are driven.

(TO BE CONTINUED.)

ON THE HEATS OF COMBINATION OF THE METALS WITH THE HALOGENS.*

BY A. P. LAURIE, B.SC. AND C.I. BURTON.

At the last meeting of the society a paper was communication by us, describing a new method for determining the heats of combination of the metals with the halogens. The following paper is an account of our preliminary experiments mentioned in the former paper. As these experiments were all made with modifications of the "iodine cell," or of the "cuprous iodide cell," we shall begin with a brief description of these two cells.

The iodine cell consists of a carbon rod and a zinc rod immersed in a solution of iodine in iodide of zinc. The cuprous iodide cell consists of a zinc plate and a copper plate immersed in a solution of iodide of zinc, the copper plate being covered with a paste of cuprous iodide, and then wrapped in parchment paper.

The E.M.F's of the cells were measured on a Thomson quadrant electrometer, the deflection corresponding to 1 volt, being found by measuring the deflection given by a Daniell cell. The Daniell cell was assumed to have an E.M.F. of 1·12 volt. This is not a strictly accurate assumption, but was sufficient for these preliminary experiments. The deflection given by the Daniell cell was measured at the beginning and end of each series of experiments. The zero of the instrument was usually noted after each deflection.

The formula used has been already mentioned. It is

$$\theta = \frac{E}{Je}, \text{ or } \theta = \frac{E}{4{\cdot}2 \times 10^7 \times e} \text{ (in C.-G.-S. units):}$$

e is equal to ·003411 grm. for zinc.

On connecting an iodine cell as above described with the electrometer, zinc as the active metal gave a deflection of sixty divisions on the electrometer scale. (The deflection given by a Daniell cell was 52 divisions.)

* From the *Proceedings* of the Royal Society of Edinburgh.

Copper, as the positive metal, gave no deflection. This was due to the coating of iodide formed on it by the iodine solution. It seems under these circumstances to be in a similar state to negative iron.

We then constructed an iodine cell in the following manner:—

In the centre of a glass vessel containing a solution of an iodide is placed a porous pot, containing the iodine solution and the carbon rod. Closely surrounding the porous pot is a cylinder of perforated zinc with which the iodine combines as fast as it diffuses through the porous pot. In this way the iodide solution in the outer vessel is quite free from iodine.

Experiments with this cell give as an average of five experiments—

Deflection with zinc, 63, in terms of the electrometer scale. As already mentioned, the E.M.F. of zinc in the ordinary iodine cell is about 60.

The difference 3 is due to an E.M.F. set up between the iodine solution and the iodide of zinc solution.

The deflection with copper is 33.

Some experiments were then made with a cuprous iodide cell constructed in the manner already described. The following table contains the results:—

Name of Metal.	E.M.F. in Iodine Cell.	Calculated E.M.F. in Cuprous iodide Cell.	Found E.M.F. in Cuprous Iodide Cell.
Zinc	60·5	30	32
Copper	30·5	0	0
Silver	29	− 1·5	0
Lead	39	8·5	10
Tin	29	...	...
Iron	31	·5	0

The second column of figures is found on the assumption that the E.M.F. of a metal in the cuprous iodide cell is its E.M.F. in the iodine cell, *minus* the E.M.F. of copper in the iodine cell.

Three has been subtracted from the numbers in the first column. The reason for doing this has been already explained. Taking 61·5 as the E.M.F. of zinc, which is the mean value, its heat of combination with iodine as calculated from the above formula is 924.

The number given by Naumann for the heat of combination of zinc with iodine in presence of water is 929.

Nearly all our other numbers agree approximately with those given in Naumann's "Thermochemie."

The numbers, taken from Naumann's table, are the heats of combination of one gramme of the metals in presence of water. It will be seen that the value given for iron by Naumann does not show any agreement with our value. This is also the case with the chlorine and bromine compounds of iron.

Reaction.	E.M.F. of Metal.	Heats of Combination, calculated from E.M.F.	Heats of Combination, from Naumann's Table.*
$Zn + I_2 = Zn\,I_2$	1·324 volts.	924 heat units.	929 heat units.
$Cu_2 + I_2 = Cu_2I_2$	·657 „	235 „	256 „
$Ag_2 + I_2 = Ag_2I_2$	·624 „	131 „	127 „
$Pb + I_2 = PbI_2$	·861 „	189 „	191 „
$Fe + I_2 = FeI_2$.	·667 „	523 „	851 „

In order to test the effect of temperature on the E.M.F. of the cell, the E.M.F. of zinc in an iodine cell was measured when the cell was at 11° C., and when it was at 27° C. The E.M.F. in both cases was the same.

* At the time this paper was read we had not seen Naumann's "Thermochemie" (published 1882). The above values have therefore been inserted since then. They are much nearer our own than the values given in the older books.

Digitized by Google

The deflection given by silver wire and silver electrolytically deposited from pure nitrate of silver is the same.

Iron wire with a blue tarnish on it gives a considerably less deflection than clean iron.

The E.M.F. given by alloys seemed to us to be of considerable interest. We supposed that they would give the E.M.F. of their most positive constituent. This, however, is not always the case. Solder gives a deflection of 40 (lead = 40, tin = 32), but brass gives the same deflection as copper, namely, 33. A confirmation of this is the fact that brass and copper give no E.M.F. in dilute sulphuric acid.

After having made these experiments with the iodine cell, we made a chlorine cell by filling the porous pot with a freshly prepared solution of chlorine. The results with the chlorine cell do not agree well with the results found in the cuprous chloride cell, and the heats of combination calculated from the electromotive forces in the chlorine cell must be regarded as very rough approximations. Two values are worth mentioning. The heat of combination of 1 gramme of zinc with chlorine, calculated from its E.M.F. in the chlorine cell, is 1,578 heat units. The number given by Naumann is 1,736 heat units. Naumann's value, with a correction which has not been made for the heat of solution of chlorine, is about 1,660 heat units. The heat of formation of $Cu_2 Cl_2$ from the E.M.F. of copper in the chlorine cell is 493 heat units. The number given by Naumann is 517 heat units.

We have made a few experiments with a bromine cell, but as we have not made any with a copper bromide cell, it is unnecessary to give them at present.

One experiment is mentioned in this paper, testing the influence of temperature on the E.M.F. of the iodine cell. This has become a matter of some importance. In a paper by Helmholtz, to which we referred in our last communication, it is shown that the difference of E.M.F. at different temperatures is possibly the measure of the work done in the cell which does not appear in the electric current.

In conclusion, the results derived from the iodine and cuprous iodide cell seem fairly satisfactory.

Probably the best way to test the accuracy of the method would be to run down an iodine cell in a calorimeter, and compare the heat evolved by the solution of a given weight of zinc with the value calculated from the electromotive force of the cell. We propose to make some experiments in this direction.

TABLE KEY, SWITCH, AND ANNUNCIATOR FOR TELEPHONIC PURPOSES.

DESIGNED BY MAGNUS VOLK.

The table key as shown in Fig. 1 has a substantial brass

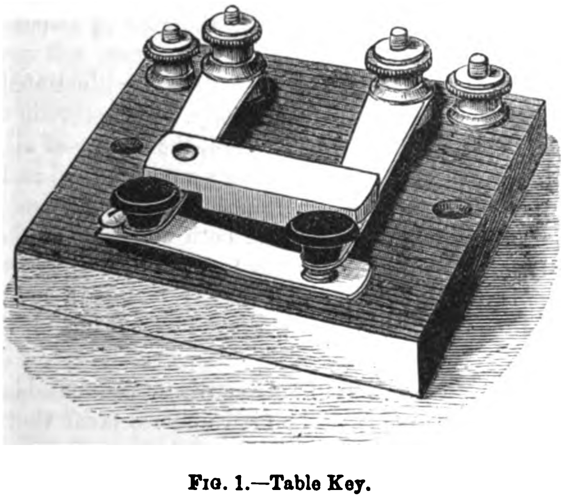


FIG. 1.—Table Key.

bridge over the keys, instead of the usual bent metal brackets, and the bottom left-hand contact (under the speaking key) is made with a spring that rises and falls a short distance so that the minute tremors of the hand may not make and break contact. The left-hand key is prevented from touching the bridge by an ebonite stud. The board is 4in. by $4\frac{1}{2}$in.

The switch (Fig. 2), which acts as a commutator, has long springs made of hard metal, and all the contacts are sliding, and very firmly made. The bottom left-hand spring is in metallic contact with the pins shown at B, but insulated from the

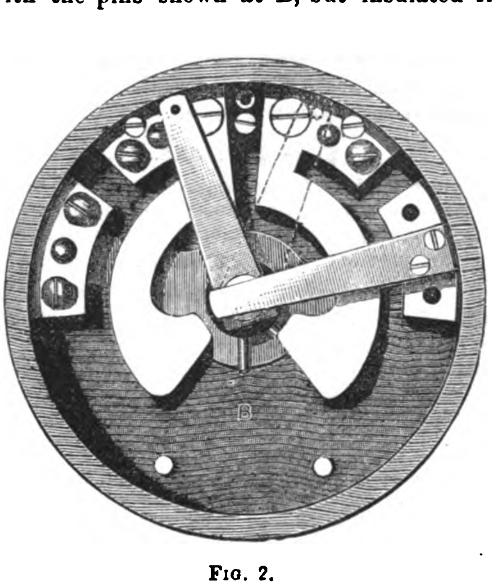

FIG. 2.

movable arm and top right-hand spring, which are in metallic contact. The blocks of the right-hand top spring should show holding down screws, the same as the other blocks. The diameter of the switch is $3\frac{3}{4}$in.

The annunciator (Fig. 3) is so constructed that there are no loose coil ends to the coils; the bolts at the back are insulated from the frame, but connected to the pins at the side, to which the coil ends are soldered, so that the whole can be

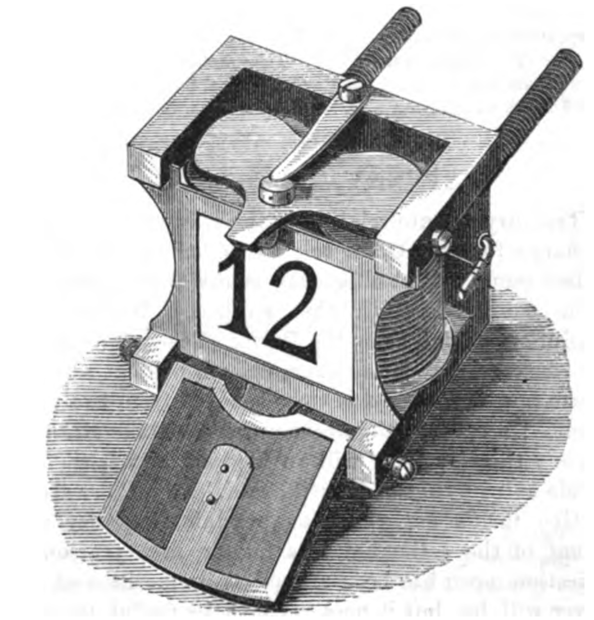

FIG. 3.

attached to a flat board and held by two nuts, the line and earth connections coming between the first and second nuts on the bolt. The card, on which is printed the number, slides into a German silver frame. These annunciators are also made polarised, which very much increases their sensitiveness. When made as illustrated, the shutter will be released through a resistance of 150 ohms, using four cells. The size is $1\frac{1}{2}$in. square by $1\frac{1}{4}$in. deep.

SIXPENNY TELEGRAMS.

The Treasury minute relating to the reduction of the minimum charge for Post Office telegrams, which we published in our last issue, will at all events narrow some of the issues raised in connection with this subject. We now know the resolution arrived at by the House of Commons in March last is to be carried out, and the minimum price at which telegrams are now despatched is to be reduced from twelvepence to sixpence; secondly, the decision will not take effect until next year; thirdly, there will in any case be a large outlay to provide extra means of transit; and, lastly, there are three alternative tariffs suggested as possible, together with a statement of the estimated loss for the first year on each. The question never has been argued on its merits, and probably never will be, but it may perhaps be useful to consider the relative merits of the several tariffs from which a choice has now to be made. The expenditure of capital calls for no remark. The estimate is not excessive, and will probably prove insufficient, but that is the Treasury's affair now that the country has decided on a measure that cannot be carried out except at great and uncertain cost. Similarly, the estimated loss arising from the adoption of a cheap tariff admits of no discussion; the only remark deserving of notice on this point being that it is a pity the people who are able to predict with such exactitude the loss on the first year have not been asked to favour us with the probable loss for all years to follow. It has long been a subject of complaint that the telegraphs did not pay their way. That they will ever do so in the future is now rendered well nigh impossible; but we are to have sixpenny telegrams instead, and it is therefore a matter of little moment whether the loss will be a third of a million, a quarter of a million, or a million. Having decided to buy our whistle we must pay for it; and this being so, the Chancellor of the Exchequer's deprecatory remarks on the "too heavy" charge involved by the adoption of "Scale 3" go for absolutely nothing.

The question, then, is which of the three scales would it be best to adopt? This, at least, would be the question if we were arguing with people who could exercise their judgment independently. But we know that crotcheteers and hobby-riders will be the final arbiters in legislation of this sort, and we must reckon with them. It is, however, a matter of congratulation that the various fancy tariffs of one kind or other put forward in *The Times* newspaper have no place in the Treasury minute, and we need not discuss them here. From the scales alone officially put forward a selection will no doubt be made. They all alike stipulate that the charge shall not be less than sixpence, however few the words contained in the despatch, and in respect to one of them provision is made that the present charge for twenty words shall not be exceeded. Sixpence for the first five words, and twopence additional for each subsequent five words, the addresses to be free, which is Scale 3, means exactly 1s. for twenty words, as at present, but leaves it open to the sender to reduce the charge by 6d., which he cannot do at present. Scale 2 includes in this charge the name and address of the sender, and would, if adopted, therefore, require a fresh Bill to amend the Telegraph Act, for the cost of twenty words of text would then exceed the present limit. The other scale, placed first in the minute as being the simplest and best understood, makes a uniform charge of a halfpenny for every word, whether of text or addresses.

The choice will probably rest between the last-named scale and Scale 3. Most of the objections that may be urged against either or both these scales apply to Scale 2. The charge for sender's address would yield very little revenue, as senders would reduce it to a mere signature, the department gaining only indirectly by the burden being lightened, whilst a portion of the public—an inconsiderable portion it is true—would feel the charge vexatious and illogical. We may here observe that one important condition in Scale 2 is left in uncertainty. If the sender's address comes first, as at present, it will be chargeable at the rate of sixpence for five words; if it comes last the twopenny rate will cover it. The absurdity of Scale 2 cannot be better illustrated than by this utterly indefensible anomaly. To a certain extent Scale 3 is open to the same objection, the charge of sixpence for the first five words of text being a very artificial and arbitrary way of obtaining the initial charge. But as seven words would ordinarily suffice for both addresses in the vast majority of telegrams, it comes to the same thing whether sixpence is charged for the first line of text or a halfpenny per word for the first twelve words, addresses included, as in Scale 1.

We say seven words would ordinarily suffice for addresses; probably even fewer would be used under a tariff that taxed them. But in practice it does not half suffice, and the difference to the revenue between a tariff which taxes all words, and one in which the text alone is taxed is enormous, for the public, while using their best endeavour to cut the chargeable words down, will proportionately be indifferent

about the number of their non-chargeable words. People of Alderman Lawrence's way of thinking no doubt are serious in regarding the curtailment of addresses as a hardship, especially to the non-commercial and poorer classes. The curtailment of the text is, however, hardly less so; and the real question turns—or ought to turn—upon whether the proposal is equitable. His own way of putting it is not equitable. It is, indeed, already "recognised that much longer addresses are required by artisans and small traders than by merchants and bankers." What is not sufficiently recognised is the undeniable fact that the first-named classes require much shorter text; and it is perfectly evident that if they are to be unrestricted in the matter of addresses, as at present, the other classes must pay for them; that is to say, pay for a privilege they do not desire for themselves, and one which the other classes would be just as well without. This is not all; the unlimited free addresses means an extravagant lengthening of every despatch, and consequent unnecessary time occupied in transmission. If the present speed of transit is to be maintained under a more popular tariff, short messages, very short messages, must be the rule. Every sound argument founded on knowledge and experience tells in favour of Scale 1; popular sentiment, however, is at present opposed to it, and probably Scale 3 is the one most in favour with people who value popularity more than wise counsel. Possibly, but only possibly, between now and next Session the public may discover that five words for sixpence does not quite realise what they expected of a "sixpenny telegram," and they may then condescend to examine an alternative proposal which, if they choose, would give them more for their money.

CORRESPONDENCE.

FIXING MAGNETIC LINES IN FILINGS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I find ordinary "sticking plaster" answers admirably for this purpose, and is better in some respects than either the paraffined paper or gummed paper arrangements.

The plaster is first pasted on a card, to be placed on the magnet when a good arrangement of filings has been obtained. A heated iron held near softens the preparation on the plaster, and causes the filings to adhere firmly on cooling.—Yours, &c., J. Brown.

Belfast.

ACCUMULATORS—A CURE FOR SPLUTTERING.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Many of your readers who have experimented with accumulators have no doubt been troubled with the spluttering from the liquid while in action. To obviate this, I should advise them to try the well-known remedy of "oil on troubled waters," viz., by covering the liquid with paraffin or petroleum oil, both as pure as possible.—Yours, &c.,

June 4, 1883. F. B.

MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am much obliged to "Sigma" for his kindness in replying to my inquiry, "How to make a make a magnetic belt." I am satisfied he has given me the very best method known, notwithstanding the irony with which his letter abounds.

I am also much indebted to Mr. Bennett for his very kind offer to give information on the application of electricity for the cure of disease, which I willingly accept, more especially as "Sigma" says the subject is worth a place in your columns. With many thanks for the insertion of my inquiry in your pages.—Yours, &c., Neuralgia.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I shall look with interest for the article in *Health* by Mr. Lant Carpenter; meanwhile I now endeavour to give in a practical way (not pretending to be scientific) the modes in which an interrupted current may exercise its medical virtues.

1. Its action as a stimulant to motor action, causing rapid contractions and relations of muscular tissue, whereby the circulation of the blood is promoted just as it is by friction or healthy exercise. Promoted circulation burns and carries away waste or diseased matter, which, if left, causes pain or even serious maladies.

We all know the history of the blacksmith's arm, and draw the inference that exercise strengthens. So it is when a weak or paralysed muscle or set of muscles is or are galvanised. Cases which have come before my notice are:—The muscles of the stomach and rectum, in cases of dyspepsia and of constipation, were made to perform their function permanently much more vigorously than before. In irregular secretion of bile, the liver similarly strengthened. In a case of deafness, the action of the eustachian tube was to a great extent restored. Where the facial muscles were weak on one side, and caused a deformity of expression, galvanising to a great extent restored the disfigurement.

Then as to cases in which by the *temporary* action of this stimulant a natural action is performed, which would not be without it, either directly or by promoted circulation. The direct action probably takes place in dyspepsia and in bronchitis. In the latter the bronchial tubes being cleared of the obstructive mucus, the patient breathes more freely, and has a better chance of recovery. The indirect action probably takes place in rheumatism and fevers.

Before leaving the subject of motor action I may mention that the muscles of the leg, arm, hand, and others (amongst them those of the urethra) may be made to respond more freely to the will.

2. A sensory action. Often do most of us, engineers and business men, return to our homes with an over-worked irritable feeling, seeming to forbid a good night's rest. In such a state I have gone to my coil, galvanised, and fallen asleep under its action.

There are times, particularly with the weaker and naturally suffering sex, when sleep gained is of no small importance.

The power to *weep* may be as important.

All her maidens watchful said
"She must weep or she must die,"

runs Tennyson's poem. The electric currents may bring about this necessary nervous crisis, as did the sight of the child.

3. Another probable cause of benefit, but which I do not insist on, is this: sometimes, between the electrodes and the skin, and I think not improbably in the tissues themselves, minute arcs are formed, and these convert a portion of the oxygen in their vicinity into ozone; this burns waste matters. Other chemical actions, too, follow an arc discharge.

4. Overcoming the resistance of skin and tissue, the currents produce *heat*. An almost infinitesimal gain repeated many times a minute may become a definite benefit in an hour. Heat is a powerful agent in removing congestive diseases, and often a gain on the principles of economy of energy.

Now, I cannot conceive the whole of these effects as a mere result of "muscular friction," as Mr. Sprague thinks them.

Further, were it so, the ratio of medical efficiency of two interrupted currents would be approximately according to their respective electromotive forces. But in practice we find the coils producing the best results are those in which a considerable quantity of wire, *not very fine*, and a low working E.M.F. are the essential features. In other words, shocks or great "muscular friction" are to be avoided in most instances.

The natural and logical conclusion is that, whatever the

Digitized by Google

cause of nervous action may be (Professor Huxley owns he does not know it, and, therefore, we cannot accurately explain its excitation), yet, as experiments go to show, the laws of the conservation of energy are here as truly, as in the thunderstorm and everywhere, the keys to unlock mysticism. To make coil construction easy, then, let us remember that in all sound electrical work our guiding principle is $C^2R = W$. —Yours, &c., A. W. BENNETT.

Black Boy Yard, Long Row, Nottingham,

HONOUR TO WHOM HONOUR IS DUE!

EDWARD DAVY AND THE ELECTRIC TELEGRAPH, 1836 TO 1839.

BY J. J. FAHIE, MEMB. SOC. TEL.-ENGS. AND ELECS.

(CONTINUED FROM PAGE 186).

Returning to our examination of the Davy MSS., we find a memorandum of another modification of the screen arrangement, which would require only two line wires (and one return wire), and yet would yield twelve elementary signals. This contrivance, which is fully explained, need not, however, detain us further than to indicate the highly ingenious plan adopted for producing some of the necessary changes of the screens. It consisted in the employment, at certain times, of batteries of *different strengths* (they being of necessity of opposite signs), so as to determine, at those times, a current of positive, or negative, sign in the return wire, and thereby actuate screens which, if the currents had been of *equal strength,* would, of course, be inoperative. This neat and effective arrangement was utilised in another of Davy's instruments, of which we must now say a few words.

fessor Faraday, who gave it as his opinion that the two inventions were distinct, the Solicitor-General quashed the opposition, and allowed the application to pass.

The *modus operandi* may be briefly described as follows*:—C, C, C, in Fig. 4, is the key-board, having three pairs of keys, so connected with three separate batteries as, on depressing any one of them (the keys), to cause a current of positive, or negative, sign, as the case may be, to flow through the line wire in connection with it, and close one, or other, of the relays at the distant end. This operation brings into play the local battery, V, whose current, setting out, from, say, the copper plate, passes through the electro-magnet, *n*, *n*, drum and chemically-prepared cloth, *a*, one or other of the platinum-tipped discs, *y*, *z*, one or other of the relay tongues according to the key depressed, and thence back to the zinc plate. The result is (1) that a mark is made on the cloth where the current passes, and (2) that the armature of the electro-magnet, on being attracted, draws an escapement from the cog-wheel, *e*, and so allows the platinum-covered drum, *a*, to revolve and carry forward the cloth through a space equal to the cross-bars shown upon it.

By sending positive and negative currents into one or more wires, variously combined, Davy was able to indicate twelve elementary signals, viz., the numerals 1 to 0, and A and Z, which, with the aid of a code-book, or dictionary, sufficed to express every word in the language, as well as a number of whole phrases, or conventional signs.

On this point Davy says, at page 117 of his specification, "three wires, A, B, and C, with two batteries, Nos. 1, and 2, will produce eight different signals, signs, or indications, and by using a third battery, No. 3, and having needles [*i.e.*, relays] applied to the common communicating wire, C, twelve different signals, indications, or signs may be transmitted, the object in using a third battery, in such case, being to give

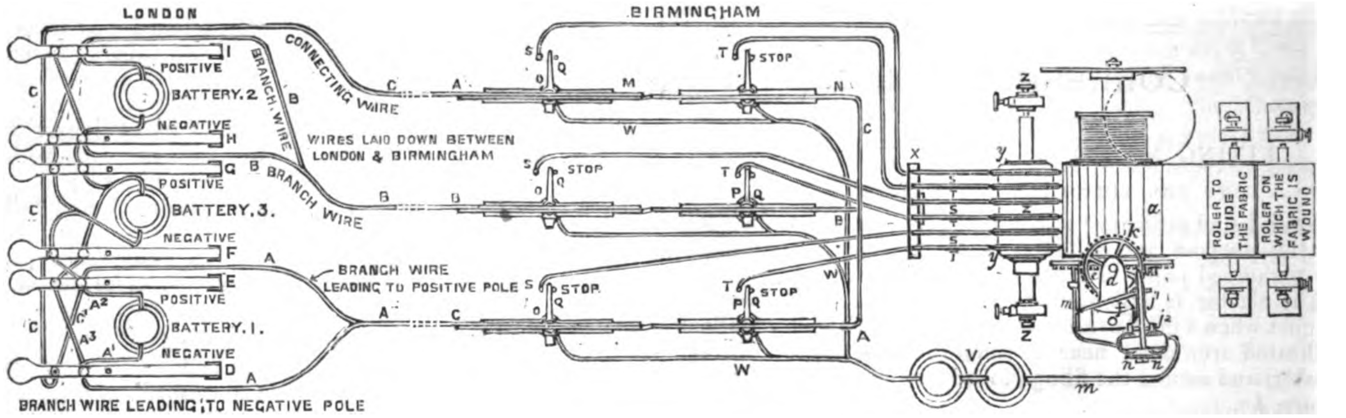

FIG. 4.

The recording telegraph is a very beautiful piece of mechanism—the first of a long line of chemical telegraphs—and we cannot help thinking that, had it had a fair start in 1838, and been fined down by practice, as it could have been, and as Cooke and Wheatstone's first inventions were, it would have given to English telegraphy an entirely different character from that impressed upon it by the rival plans, and chemical telegraphs would now be the rule instead of the exception.

Like all his other inventions in telegraphy, Davy perfected this apparatus before December, 1837, or, as he says in his "Statement," before the enrolment of Cooke and Wheatstone's first specification, of the nature of which he was, at the time, in perfect ignorance, "except in so far as it could be gathered from paragraphs in the newspapers, which conveyed really no information."

He wished to take out a patent at once for this instrument, but, owing to legal formalities, and the opposition of Cooke and Wheatstone, the specification was not sealed until July 4, 1838. The opposition appears to have been based on the plea that some parts of Davy's mechanism were infringements of their patent of June, 1837,* but, on a reference to Pro-

* Davy's MSS. contain some warm passages on this most unfair charge.

greater quantity of electricity to certain currents; thus, supposing a positive electric current to be passing through the wire, A, and a negative electric current to be passing through the wire, B, there would be two electric currents passing to the wire, C, in opposite directions, consequently the needles [relays] on the wire, C, would not be acted on in such manner as to obtain a certain and definite indication, or signal, unless the positive, or negative, current passing to the wire, C, be made more powerful than the other, and this may readily be effected by the keys, F, G, which can bring the wires, A, C, B, C, in connection, or metallic communication with the battery, No. 3, in addition to their own battery, and thus give more power to one of the currents passing through the wire C."

Following the original drafts of this apparatus, which are preserved amongst the Davy MSS., we find a description of another telegraphic project, which, as our readers will observe, is based on the same electrical principles as the diplex and quadruplex systems of the present day. It is a mode of obtaining one, two, or more signals through a single pair of wires by means of currents of one, two, or more degrees of

* Those who desire a fuller account will find it in the specification which can be obtained at the Patent Office for a small sum. It contains all the accessories of a complete telegraphic system, many of which have already been described in these pages.

Digitized by Google

strength, acting on needles so weighted as only to respond to the currents destined to move them.

For the signal-indicating part of this plan, Davy proposed to employ a new form of galvanometer, which he called an "electro-magnetometer," and which he had designed, in the first place, "for measuring with greater precision than heretofore the exact quantity of electricity passing in any given circuit." This instrument is figured and described in his patent of July 4, 1838, pages 16-17.

Foreseeing that to operate a telegraph of this kind it would be necessary to regulate, and keep regulated, the currents with great accuracy, Davy devised, for this purpose, a very beautiful "self-regulating galvanic battery." "The principle of the contrivance," to quote his own words, "is that as soon as the magnetic energy of its electric current rises above, or falls below, a certain required standard one of the metals of the galvanic pair is, by the agency of this magnetic energy, either raised out of, or further depressed into, the acid, or exciting liquid, in the cell; so as to become, thereby, less, or more, exposed to the action of the liquid; the extent of its exposure regulating the quantity of electricity generated.

"To effect this intention, there are two coils in the conducting wire proceeding from the battery:—in which are two of my electro-magnetometer needles. Of these needles the dipping end of one is a certain degree heavier than that of the other; and the intention is that the electric current should remain within the limits of the two; so as just to act upon the lighter: but not on the heavier.

"Now, if the current be too powerful the heavier needle, by dipping, will cause a communication between a fresh, or distinct, source of electricity and the two wires *a*, and *b*, attached to platina plates in dilute sulphuric acid contained in the air-tight tube, *c*. Then by the decomposition of the water, gases will be evolved, and depress the liquid at *c*, and also the mercury below it, *d*, so as to elevate the piston, *e*, and its rod, *f*, whereby the lever, *g*, is also elevated, and lifts the metallic plate, *h*, belonging to the galvanic battery, so as to diminish the energy of the said battery to the required degree.

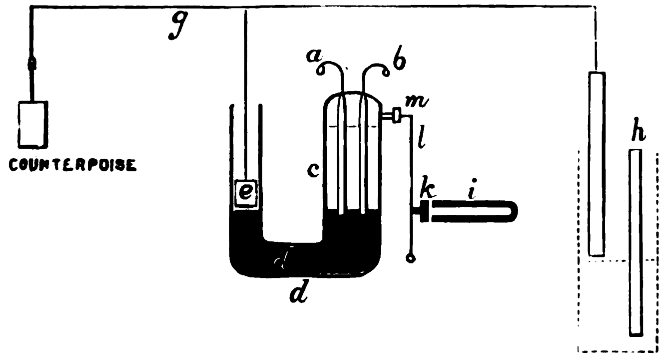

Fig. 5. (Drawn from original manuscript.)

"If, on the other hand, the electric current be too feeble, then the lighter needle will fall and open a communication with the distinct source of electricity through the coil of wire which surrounds the electro-magnet, *i*, whereby it is rendered temporarily magnetic and attracts the piece of iron *k*, which, thro' the lever, *l*, removes a caoutchouc (or other suitable) stopper from the minute aperture at, *m*, so as to allow the gas in the tube, *c*, to escape until the metallic plate, *h*, has again sunk sufficiently into the liquid in the battery cell to generate the required, or standard, quantity of electricity, such standard being allowed to vary between these minute differences only.

"Having thus obtained the element of a uniform battery, the quantity of electricity to be transmitted thro' the circuit may be regulated either by the number of such batteries uniting their currents, or else the current from one battery may be divided, and the mode of so dividing it is the remaining consideration.

"The electric current may be made to travel thro' pieces of platina, or other wire, of different diameters, and of given lengths, so that the thicker the wire, the greater will be the quantity of electricity to pass:—the exact dimensions of these to be regulated by actual experiment,* and, in order to obviate their ignition and combustion, they may be arranged under water, or, should water be objectionable, under some non-conducting, and non-electro-decomposable liquid, such as sulphuret of carbon, or naphtha, or whatever other may be found advisable."

From amongst Davy's miscellaneous memoranda we select two or three, with which we must close this portion of our work. In the first our readers will, we doubt not, be amazed, as we were ourselves, to find how near the writer was to discovering the telephone in 1837-8.

"19. The plan suggested (100) *where the signals are shown by reflection.*

"20. The plan proposed (101) of propagating communications *by the conjoint agency of sound and electricity—the original sound producing vibrations, which cause sympathetic vibrations in a unison sounding apparatus at a distance, this last vibration causing a renewing wire to dip† and magnetise soft iron so as to repeat the sound, and so on, in unlimited succession.*"

The sheet from which we copy these remarkable words is headed "Exclusive Claims," and seems to have served as an *aide memoire* to the drawing up of his patent specification. If our surmise be correct it would fix the date of the paper as not later than the beginning of February, 1838, for we shall see, later on, that he was, in that month, submitting his inventions to Mr. Carpmael, a well-known patent agent of that period. Unfortunately we can find no further mention of the "plan proposed," and can only surmise that Davy designed some kind of telephonic relay.

In the following memorandum the writer could only have in view a form of cell, which is now so well and so deservedly esteemed under the name of its recent inventor, M. Leclanché:—

"*A New Galvanic Battery,*

"A particular mode of using oxide of manganese as the electro-negative element of the battery, or in connection with the electro-negative plate.

"Certain other improvements in the battery, which will be described, if there be any opposition on this head,

"*An Improved Magneto-Electric Machine,*

"To be described if there be any opposition on this head."

The following extracts are from a paper headed—

Elemental Forces and Alarums.

There are two objects for which alarums may be required as essential appendages to the Electrical Telegraph.

1st. To give notice that communications are about to be sent, and call the attention of the person who is to receive them. For this purpose alarums of great loudness will not generally be required, unless the party be asleep, or not in the same room, and even in these cases a moderate loudness will suffice.

2nd. To give notice of accidents on a railway, or in other cases where the alarum may require to be heard by persons who may be at a distance at the time.

1st. With the first object an alarum is easily made. One of my horizontal dipping needles (surrounded by its coil), may have an upright rod, as a radius from its axis, with a little hammer on a spring, to strike a small bell by the deflection, or dip, of the needle. Thus two needles in the same wire may strike two distinct bells and produce a kind of chime; either one, or both, or variations of which, may be advantageously used according to the intention of the alarum.

* * * * *

2nd. Whenever an almost irresistable, or, at least, very great power is required, either to produce alarums, or for any other purpose, I claim the following mode of effecting

* Here we have the rheostat, or set of resistance coils, as used at the present day.

† *i.e.*, causing a relay to close a local circuit containing an electro-magnet. Davy always speaks of the relay as the "renewer," or the "renewing wire." By dip he means to dip into mercury, or, as we say nowadays, to close the circuit.

Digitized by Google

the object, which is also applicable in other cases where temporary magnetisation may prove insufficient.

A piece of platina wire, *a*, connected with the opposite poles of the conducting wire, *b*, and *c*, is securely enclosed in an air-tight, and strong vessel, *d*, *d*, in contact, or proximity, with a quantity of sulphuret of carbon, or other suitable volatile liquid. Then the current of electricity from *b*, to *c*, will ignite, or heat, the platina wire *a*, so as to convert a portion of the volatile liquid into vapour, which will then

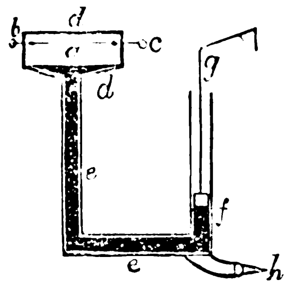

FIG. 6. (Drawn from original manuscript.)

expand with a degree of force, proportioned to the heat of the platina wire, and its continuance in a heated state. This will force the mercury, which is below the volatile liquid through the tube *e*, *e*, so as to elevate the piston at *f*, and *g*. The force thus obtained may be applied to any required purposes.

When the current of electricity ceases to pass, the sulphuret of carbon, or other volatile liquid, will re-condense, and the piston gradually resume its former position without the necessity for an attendant to liberate the vapour. Of course a safety valve may be attached, if necessary, either at *h* or at *d*, *c*, and the self-regulating battery would be useful in combination with this contrivance.

A continuous sound may be produced by applying either of the above-mentioned forces to open a valve so as to admit air, or gas, from a vessel containing such air, or gas, under compression through a whistle, horn, or other wind instrument. Air, or gas, under compression for this purpose may be provided by the action of dilute sulphuric acid on old iron, on the principle of the hydrogen instantaneous light apparatus, where, as soon as a certain quantity of gas is generated, the liquid is forced into another part of the vessel so as no longer to act on the metal; or air may be pumped in from time to time.'

As we have frequently in the course of these pages referred to Davy's "Statement," we think it advisable to reproduce this important document, as, while confirming our chronology, it will also serve as an excellent *resumé* of the writer's leading discoveries :—

Statement.

The idea of an electrical telegraph first occurred to me about the year 1836, at which time I was not aware but that it was perfectly original. In the commencement of 1837, having tried some experiments with a mile of copper wire in the Regent's Park, aided by my friend, Mr. Grave, I entered a *caveat*, in March, and, about the same time, I deposited with Mr. Aikin, Secretary of the Society of Arts, a sealed description of my invention, in its then state.

My earliest idea of applying the deflection of the needle for telegraphic purposes, was similar to that since claimed as a new invention by Alexander, with a common return wire. The next improvement was the obtaining the two actions upon each needle by the reverse currents. Then, the fixing two, instead of one needle, in each circuit, and subsequently, the system of permutation described, with the use of the colour needles, and the employment of more than one battery. It was at this stage (in March 1837) that I first heard of Professor Wheatstone being engaged in the same subject, which led me to enter the *caveat*. Shortly after this, the idea of the renewing needles [relay] occurred to me. This was after a conversation on the subject with Mr. Bush of the Great Western Railway.

In May 1837, Messrs. Cooke and Wheatstone applied for a patent, to which I entered opposition, having provided myself with a written description of my inventions, and prepared to attest it by the evidence of several confidential friends. This evidence will be partly direct, and partly corroborative. I have Dr. Grant, Mr. Thornthwaite, and Mr. Hebert, besides the workman who helped me to make the models, and the Solicitor-General, on some specific, but all-sufficient, points. The paper was carefully inspected by my friends, who were also present at the hearing on the opposition.

The Solicitor-General at the time gave an opinion that the two inventions were different, and allowed the patent to pass: although time has since shown that they contained some of the clearest identities.

My remedies for the injustice thus sustained are, that I may move a writ of *scire facias* to set aside and annul Messrs. Cooke and Co.'s patent, on the ground that the Crown was misled in granting it,—or else, or after failing that, to act upon the [my] invention so that they may bring an action for infringement, which I have ample grounds for defending, and the failure of which will *virtually* render their patent void.

Litigation of this kind, which will be highly injurious to one party, and but partially beneficial to the other, is what it is in every way desirable to avoid, if the matter can be otherwise adjusted.

From the time of this decision (May 1837) up to the time of the enrolment of their specification in December, I was in perfect ignorance of the nature of their invention, except in as far as it could be gathered from paragraphs in the newspapers, which conveyed really no information.

In the meantime I introduced into my plans first, the use of screens, then the means of determinining the signals to specific places exclusively, and finally, that which I believe is calculated to supersede all others, the recording telegraph by electro-chemical decomposition.*

As showing Davy's wonderful perception of the uses which the telegraph would subserve, as well in the internal economy of railways, as in the political economy of the nation, and of the world at large, we give below the concluding portion of a lecture, which bears evidence of having been written about the middle of 1838,† but which appears never to have been delivered :—

"The point which now remains for consideration is, of what use will this electrical telegraph be? What are its applications, how will society at large benefit from it, and what inducements does it hold out to private adventurers to take it up as a means of investing capital?

"Now, at the outset of nearly all new propositions of this nature, there are two kinds of objections which we have to contend with. The first arises from the circumstance of the invention being a novelty, and different from all that people have previously been accustomed to. We get laughed at; the matter is treated as a dream. 'Really, sir,' says one, 'you cannot be serious in proposing to stop the escape of a thief, or swindler, by so small an electric spark, acting on a needle; if you had talked of sending a thunderbolt, or flash of lightning, after him, I might have thought there was some feasibility in it.' Another tells us that the experiments are very well across a room, but would not succeed on a large scale. Then, as soon as the practicability of the thing is undeniably established, the same people turn upon us with the question, 'What is the use of it?' There must be some present who will recollect that the first introduction of gas was beset with the same objections. So also were the railroads, and to a certain extent they continue to be up to this time. So also was the steam engine, printing; in fact, almost everything new is discountenanced, or coldly received, by the public at large in the first instance. However, the time has, I believe, already arrived, when the practicability of this electric telegraph is no longer doubted, either by scientific men, or by the major part of the public, who have

* To this may now be added (1) a block system for railways, (2) the telephonic relay, and (3) the oxide of manganese (Leclanché) cell, besides numberless suggestions of a more or less practical nature, many of which are described in these pages.

† Referred to in his letter of 16th June, which see *infra*.

Digitized by Google

given any attention to the facts upon which the invention rests.

"I have, therefore, to confine my remaining observations to the uses and application of it. And first, I have a few words to say upon what must be considered as a minor application, namely, the purposes it will answer upon a railway, for giving notices of trains, of accident, and stoppages. The numerous accidents which have occurred on railways seem to call for some remedy of the kind; and when future improvements shall have augmented the speed of railway travelling to a velocity which cannot at present be deemed safe, then every aid which science can afford must be called in to promote this object. Now, there is a contrivance, secured by patent,* by which, at every station along the railway line, it may be seen, by mere inspection of a dial, what is the exact situation of the engines running, either towards, or from, that station; and at what speed they are travelling.† Not only this, but if two engines are approaching each other, by any casualty, on the same rails, then, at a distance of a mile or two, a timely notice can be given in each engine, by a sound, or alarum, from which the engineer would be apprised to slacken the speed; or, if the engineer were asleep, or intoxicated, the same action might turn off the steam, independent of his attention, and thus prevent an accident.‡

"I cannot, however, avoid looking at the system of electrical communication between distant places, in a more enlarged way, as a system which will, one of these days, become an especial element in social intercourse. As the railways are already doing, it will tend still further to bring remote places, in effect, near together. If the one may be said to diminish distance, the other may be said to annihilate it altogether, being instantaneous. The finger of the London correspondent is on the finger key; and, anon, in less time than he can remove it, the signal is already on the paper in Edinburgh; and almost as fast as he can touch one key after another in succession, these signals are formed into words and intelligible sentences. These may either have private interpretations attached to them, easily arranged between individuals, or they may be translated according to rule by a clerk of the establishment, supposing such an establishment to be instituted and thrown open to the public like the Post Office, on the principle, that any one might send a communication on paying some moderate fee, to be charged according to length. All the practical details of such an establishment are easily chalked out.

"Now, how far would there be sufficient employment, or business, to remunerate the projectors, and how far would the public at large be benefited? Premising that it is a very shallow supposition to consider it as facilitating monopolies, inasmuch as it would be open to all, the first question is, what would be the cost, or original outlay, on a very complete system? I believe about £100 per mile. That would be £10,000 from London to Birmingham, and about £10,000 more, making £20,000, to bring these towns into communication with Liverpool and Manchester.

"Now, if there be 2,000 miles of railway altogether open, or likely to be open ere long, then the capital requisite to carry such an enterprise generally throughout the kingdom would be £200,000, or about $\frac{1}{15}$ of what has been expended on the London and Birmingham Railway alone. Let us first confine ourselves to the line of communication between the four great towns, London, Liverpool, Manchester, and Birmingham, at an outlay of about £20,000. The repairs, when once laid down, would be very inconsiderable, and very rare. The annual expenses, beyond the interest of the money, would be almost confined to the clerks and superintendents of the establishment, making a total, which, for argument's sake, we will call £2,000, or £3,000 a year. Whence will be the revenues to cover this expense, and leave a profit?

"In the first place, there is a certain amount of staple employment, which would be daily and regular. We should inevitably have to communicate the prices on exchanges, the market prices of commodities, rise and fall in stocks and shares. There would be the earliest information of commercial stoppages, arrival of ships with cargoes, and their departures. Then there would be Lloyd's shipping list, as a matter of course, Government dispatches, and certain portions of banking correspondence and announcements. Lastly, among the best regular customers would be the newspapers. Public curiosity upon events of importance would ensure that the press would generally get the earliest possible information for their readers, and competition alone would oblige it. There are certain events which would be communicated by telegraph to all the principal towns in the kingdom for publication in the newspapers, as regularly as the publishing day or hour came round. There would be Parliamentary divisions, results of elections, public meetings, criminal news, results of trials of general interest, and the earliest foreign news of all kinds. So much for the regular employment.

"But I conceive that the occasional employment of individuals, for private family correspondence, or for purposes of business, would make up in the aggregate even a far greater amount. Here it is quite impossible to see how multifarious may be the occasions on which such a means of rapid communication would be of vital moment. Let any individual reflect whether in the course of his life, whether in the course of the past year, there has not been more than one occasion when he would eagerly have availed himself of it, if it had been in existence? Generally speaking, we know that the post is fast enough, and often letters are sent by private hands, when they are many days delayed, and it is of no consequence. But such occasions there are, and though, for argument's sake, I suppose them rare, yet in reality they are not so. If in the population of London, upon an average, only one private person in eight employed the telegraph only once in six months, and received an answer by the same means, at no higher charge than the present postage, say 1s., here we should have at once a revenue of £40,000 a year, which I take to be infinitely within the mark.

"Now, what are the occasions on which private individuals would prefer the telegraph to the post? Let us say to announce a birth, or marriage, in a family connection, a death, or sudden illness. No one would be satisfied to convey intelligence of such an event to anxious relatives by any other than the most rapid communication, and if the medium was in existence they would be expected to use it. If one death in ten which take place in London were communicated by telegraph, and that to only one person at a distance the amount of income from this single cause alone would exceed £1,000 a year. Announcements of dangerous illnesses, and daily communications thereon, which would often be transmitted, would considerably exceed even that of the deaths. But this is not all; all sorts of family events, besides births, deaths, and marriages, transactions of business, urgent communications between commercial travellers and their principals, errors and oversights to correct before too late, all these would be of no very unfrequent occurrence in every family, or business firm, and taken on the whole, among the great population of this active nation, they would supply the telegraph with as much employment as it could well get through.

"But now some one will say, supposing it all very true that these things can be done, supposing that it will pay very well to speculators, of what advantage will it be to society at large? Railroad travelling is quick enough in all conscience; people used to say that stage coach travelling was quick enough; and some years before that, they were no doubt very well satisfied with the waggons. Now here is a means of communication compared with which the railroad travelling is as a snail's pace. The electrical telegraph can be considered as only one means of facilitating intercourse between distant places; and it is adapted for occasions where all other means would fail. It will in some respects give to persons living at remote distances the same advantages as if

* In the drawing up of the final specification all mention of this invention was, most unaccountably, omitted. This enabled Wheatstone in 1840 to patent a similar step-by-step instrument, with dial face, &c.

† At every railway station there will be a dial, like the face of a clock, on which, by means of a hand, or pointer, it may be seen where any particular train, running, towards, or from, that station, may be at an particular instant. Every time the engine passes a milestone, the pointer on the dial moves forward to the next figure, a sound, or alarum, accompanying each successive movement.—Davy MSS.

‡ The most perfect block system of the present day does not do anything like this.

Digitized by Google

they lived in the same street. Should the system ever be adopted generally throughout Europe, what a vast field does it not open to us. Whatever is going on in Turkey, or in Russia, may be known in London the same hour; and, though it may seem a bold speculation, I can see no improbability that this will be realised wherever the line of country admits of it. In fact the greater the distance the more valuable in proportion will be the information communicated.

"Goods ordered from a distant country will, of course, arrive in just half the time they otherwise would, because the outward voyage, or journey, for carrying out the order by letter is dispensed with. On general principles, whatever tends to promote intercourse between distant countries, or distant parts of the same country, will inevitably promote civilisation and increase the comforts of life.

"I must now conclude by stating that the electrical telegraph is already in progress of being established through a considerable line of this country, and there is every encouragement for supposing that it will, without delay, be brought into operation on a still more extended scale. I trust, therefore, that the company present will live long enough to see that, while we have not presumed to use the thunderbolts of Jupiter for destructive ends, we have acquired a command over the same electrical principle, for purposes infinitely more beneficial."

Having now given a full and impartial account of Davy's many and wonderful discoveries in electric telegraphy, it will be interesting to follow him in the steps which he took to get his inventions adopted. For this purpose we must turn to another class of his MSS, viz:, his private letters to members of his family, and chiefly, to his father, Mr. Thomas Davy, Surgeon, of Ottery St Mary. In the extracts which we shall give from these the reader, who knows anything of the similar negociations of Cooke and Wheatstone during the same period, will find some startling revelations.

At one time his inventions were on the point of being adopted by more than one English Railway, and, had he stood his ground but six months longer, there can be no doubt that he would have eclipsed his rivals, so that to-day we should hear more of Edward Davy and somewhat less of Cooke and Wheatstone, But alas! just as his labours seemed on the point of fruition, private affairs, which we can never cease to deplore, drove him from England, and, of course, left his rivals an easy triumph, Davy sailed from the Thames for Australia, on April 15, 1839, and, amid the new cares of a somewhat unsettled Colonial life, soon forgot all about the telegraph. Indeed we believe that nobody will read our memoir with more surprise than the old man himself who is the subject of it.

The first extracts that we shall give have reference to the Exhibition at Exeter Hall, referred to on page 185 of this Journal. In a letter to his father dated January 23, 1838, he says:—

"I write you a few lines in haste, upon a different subject from the last. By the advice of several friends, whom I have deemed trustworthy counsellors in such matters, I have been induced to open an exhibition of my electrical telegraph, accompanied with electrical and galvanic experiments of a somewhat novel nature to illustrate its principle.* You will observe that the present apparatus is, in appearance and effect, totally different from what you have seen, though founded on similar elementary principles.

"The degree of success of the last three days has been sufficient to encourage me in the correctness of what I have done. I have had Captain Beaufort from the Admiralty to look at it, as well as Mr. Jay, who is superintendent of the Government telegraphs, and who invited me to the Admiralty to-morrow, to examine the telegraphic arrangements, and furnish me with an exact estimate of the expenses of the present system for the sake of comparison. This I think a good introduction. To-day I have had 18 persons, paying their 1s. each, and yesterday 12, to see it, several expressing themselves gratified, and saying that they should bring their friends to see it. An old gentleman came yesterday, and to-day he came again with four ladies. He says he is coming again to-morrow with some male friends and others.

"On the principle, *parvis componere magna*, I am led to presume that if the thing were generally known (instead of being merely left to the attraction of a board or two at the door) a great many persons would come to see it, paying their 1s. each, and that thus I might realise a considerable sum [which would be] very acceptable. To make it pretty generally known is impossible without some expense which, at present, it is out of my power sufficiently to compass. And yet the thing appears to me so promising in success, that I would not willingly lose the chance, after having bestowed so much care, anxiety, and labour on the invention, and having, as I have now the best reason to believe, brought it to greater perfection than any other person. It is my anxious wish, now that every principal expense has already been met, immediately to advertise the exhibition, once or more, in every principal newspaper, and to take other necessary means of making it public. From present experience I believe the returns will be speedy, and in any case the prospect of indirect advantage to me is sufficient to justify so doing. If I neglect, or am unable to avail myself of, the present opportunity, there are others ready who will instantly take it up.

"Clarke, Palmer, and Cooke himself have been to see it at the private exhibition on Thursday last, and though they could not *immediately* make out the principle on which the effects were produced, yet it is all come-at-able by dint of pondering and patient experiment by such long-headed persons.

* * * * *

"From 11 to 5, exhibition hours, I have scarcely had time to warm my fingers in the late bitter weather, from the all-sorts of questions, explanations, illustrations, demonstrations, &c., I have had to deal forth to the learned and unlearned—the former being the least troublesome."

A few days later he wrote to the same address:—"The exhibition to-day had about the same number of visitors within 2 or 3, which, all things considered, is pretty well, and, if continued, would set aside all apprehension of losing by it.

* * * * *

"Among the visitors were Lord Euston and his son, who were pointed out to me by a gentleman present. Mr. James Wheeler, my old master's brother, was there. He was at a lecture at the Royal Institution last week, when Cooke and Wheatstone's telegraph was exhibited, and said that, on comparison of action and effect, he much preferred mine. He also said that theirs would be rather advantageous to me than otherwise, as the public would soon draw the parallel.

"It is my earnest desire now to make the thing promptly known in every direction [by advertising largely].

* * * * *

I calculate that by the time 1,000 persons have been to see the telegraph their retail conversation will be enough to dispense with other advertisements than rare and occasional ones, because, out of 1,000 persons on an average computation, 100, by their gossipping propensities, will act as walking advertisements.

"I have with me a boy who is remarkably sharp and handy at repeating the experiments. * * * * The little fellow appears to be able to understand anything he has once seen, and has, moreover, a very good address, asking for the One Shilling, Sir, or Madam, very genteely, &c.

"You did not expect to have a son turn showman, but I trust I am merely instrumental in promulgating a useful discovery, and that you will live to see it established, generally, throughout the country. I must *endeavour* to persuade the Admiralty to lay it down from London to Chelsea, or Putney, for experiment, this being the most foggy part of the line towards Portsmouth; but I fear they are too stingy of the revenues of the nation. I rather expect that some enter-

* "This exhibition is accompanied with a variety of interesting experiments, the room *lighted by an enormous galvanic battery*, and, altogether, I have seldom passed an hour more amused." Extract from letter in *Mechanics' Magazine*, for February 3, 1838, p. 296.

Digitized by Google

prising individuals will take it up for public use. Time will show.

"P.S.—Receipts to-day about 25s. Among the visitors was pointed out, after he had left the room, Earl Grosvenor."

Towards the end of February, 1838, he wrote :—

My Dear Father,

My business with Mr. Welch is concluded—my lease cancelled—and I am no longer the occupier of the house 390, Strand. Please, therefore, address to me at Mr. Smith's, 199, Fleet-street.

* * * * *

As we some months ago prognosticated, the telegraph, being once promulgated, has interested the public, and is in a fair way to be generally adopted. The Great Western Railway have decided upon laying it down upon their line, and the only question, both in this, and in all subsequent cases, will be, whether my plan, or that of Cooke and Wheatstone, be preferred.

Mr. Brunel, Junior, Engineer to the Great Western Railway, with Mr. Tite, and other Directors of the company, came to see my apparatus, and wished me distinctly to point out the advantages which it possessed over the rival scheme. Mr. Brunel, being on intimate terms with Mr. Cooke, was somewhat inclined to lean the other way, but the principal difficulty under which I laboured was the impossibility of rendering manifest all the advantages of my mechanism, without entering, more or less, into such explanations as would, more or less, betray my secret—as yet unpatented. When, therefore, I stated that I could effect such and such objects he could not see how it was possible—thought the attempt would be dangerous, or precarious. Seeing also that I employed six wires he could not conceive but that my plan must be an infringement upon the patent of Cooke and Wheatstone, and that the company could not safely carry it into execution without risk of action for damages, &c.

Moreover, that, as I was not prepared fully to develope my plans, I could not be considered in a condition to treat with them, for they would have to buy of me what he designated "a pig in a poke," which, though it might produce very pretty effects, yet, as the *rationale* was not open for canvass, its practicability could not fairly be judged of, nor could he confidently assure the company but that it might prove to be an infringement on the others' patent. Mr. Brunel is a particularly sharp, intelligent man, capable of comprehending anything in all its bearings, and of improving the barest hint. I had, of course, to be on the alert to divulge nothing that would impair the security of a future patent-right. I could not fail to learn something from him, and the result of this interview has been to prove to me the necessity of ascertaining, with the greatest care, the precise footing upon which I stand, before taking any further steps. I have endeavoured to persuade the company to delay a week, or two, before they ultimately decide on adopting any plan.

In the meantime, my first object will be to obtain the opinion of the most eminent lawyer in patent affairs, and I have been nearly all this day engaged in conference with Mr. Carpmael upon the subject. This may cost me two or three guineas, but will be infinitely cheaper than a blindfold course of proceeding. To-morrow I shall get his opinion. Should this be favourable to my views, I shall almost think it right to obtain a second opinion of some eminent barrister, or of the Attorney, or Solicitor-General, before venturing to act upon it. But if fully confirmed as to my right to secure as exclusive, and to act upon, or license others to act upon, my own invention, there can be little question as to the peremptory necessity for immediately raising funds to take out a patent, which will place me on a par, or more than a par, with Cooke and Wheatstone. The time has now arrived when the thing is on the point of being acted upon throughout Europe.

As to the particulars of my mechanism, there are guesses enough at it, but, though it is simple as can be, the guesses are as far wide of the actual truth as need be. Mr. Cooke himself is in perfect ignorance of it.*

I hope, in a postcript, to subjoin Mr. Carpmael's opinion. He told me this evening that, though he would not record it on paper until he had investigated the matter fully, yet his present impression was that the two inventions [*i.e.*, Cooke and Wheatstone's and his own] differed most essentially in all main points, and that a separate patent might be obtained and maintained without hazard of litigation. He has appointed to-morrow morning to inspect my mechanism (of which as yet he has seen the description only) at 10 o'clock, at Exeter Hall.

28 February, 1838: I enclose a copy of Mr. Carpmael's opinion.† I am now passing the patent through the first stage, which will cost about £12, but beyond this, unassisted, I shall not be able to go. Mr. Carpmael thinks it may not be difficult to get some one to advance money for future patents, if I can only place myself in a condition to explain, by securing the English patent first, after which it will be just as desirable to do the same thing in Belgium, America, and other places.

* * * * *

Your ever affectionate son,

E. Davy.

My Dear Father: This long-pending decision upon my application for a patent has at length been given. I believe I told you that, owing to the Solicitor-General not being able fully to comprehend some points, it had been agreed to call in the assistance of some eminent scientific man, and, accordingly, Mr. Faraday was referred to as being the highest electrical authority in the kingdom, and he was kind enough to undertake [the examination of the points in question]. The result has been in my favour, *i.e.*, I am entitled to the patent I am applying for with the retention of every point of the least value. The Solicitor-General's report will be ready for delivery to-morrow, Thursday, and then all that will be wanted to proceed with the patent will be the money. It will then take about ten days to pass the great seal, and until that there is no security for it, and I will still labour under the difficulty of not being able to explain its nature, or advantages, to any one so as to get it taken up. Besides, there is every day the risk of persons finding out the particulars for themselves.

Once the patent secured, I think it not improbable that it may end in a compromise with Cooke and Co.,‡ for when I have the patent I must get connected with some one possessed of capital. They have, I understand, already laid out £2,000 upon their telegraph, and are very anxious at present, as Mr. Wheatstone told me they were in treaty with some of the great railway companies, but that the latter delayed coming to a decision, understanding that there might probably be another patent in the market. So, if I pass my patent, they will either have to wait six months to see the specification, or else offer me terms at once.

Whether the Great Western is the company alluded to I know not, but I had previously been given to understand by Mr. Gibbs that they had already contracted with them, and were going on with the preparations (as I was told by a a different party) of coating an immense quantity of copper wire with india-rubber. It may, therefore, or may not, be some other great company.

I am happy in being able to communicate the intelligence contained in this note, for, from the long and vexatious delay, I have been not without apprehension that the decision would be against me. The circumstance of Mr. Faraday having been called in will also render the patent safer, as his opinions

* "I have sufficient reason to know that the true principle of [my apparatus] has not been discovered by anyone, not even by Mr. Wheatstone. I have purposely, and for a veil, allowed it to be supposed that the principle is the same as that in Mr. Cooke's invention, which, as I designed, is taken for granted." Davy MSS.

† This document, copied by Davy himself, is preserved amongst his MSS. It bears the date February 24, 1838.

‡ This is what exactly did happen eventually—the patent was bought up for £600 by the old Electric Telegraph Company, and smothered, like a good many others.—See letter of May 12, 1847, amongst the Davy MSS.

on such matters would naturally be looked upon by the public with some confidence.

* * * * *

With kindest loves, believe me,
My dear Father,
Your ever affectionate Son,
E. DAVY.

30 May, 1838.

P.S.—I enclose a copy of the claims upon which Mr. Faraday advised that my patent might be granted. You will perceive that it contains the most important points.*

(TO BE CONTINUED.)

ON THE PENTANE STANDARD, AND ON A NEW FORM OF PHOTOMETER.†

BY A. G. VERNON HARCOURT, M.A., F.R.S.

(CONCLUDED FROM PAGE 189.)

Early in the present year the attention of the Metropolitan gas referees was called by Mr. Wates, the engineer in charge of the Vauxhall station of the South Metropolitan Gas Company, to a persistent difference between the return of the illuminating power of the gas from the testing place at Clapham and the testings of the same gas at Kennington, where it is stored. To gain further evidence, a set of testings was made alternately and in quick succession by the same observers at the gasholder station and at the testing place. The testings were made with a jet photometer and a pair of candles carried backwards and forwards. The results with the candles, obtained with the greatest care, were too discordant to be of much value; but both they and the more trustworthy indications of the jet photometer confirmed the former experience.

The planning of these testings suggested the desirability of giving to the pentane standard a portable form. In this form the flame is still an air-gas flame produced by mixing in the reservoir of the lamp the vapour of pentane with air. The mixture, being heavier than air, floats over the liquid; its composition varying in each layer from a very rich gas, at the surface of the pentane, to air into which little or no pentane has diffused, beneath the lid. It is clear that by tapping this stratified mixture of gases at the proper level an air gas containing 3 volumes of air to 1 of pentane—the same that is made up in the gasholder—may be drawn off; the same mixture being constantly produced at the same level by evaporation and diffusion of pentane vapour from below, and inflow of air from above. With a reservoir and outlet as small relatively to the flow of gas as have here been made, if the gas were visible a whirlpool would be seen, the separate threads of air and pentane not blending entirely until they have been drawn into the pipe. But no matter how the gases enter, the mixture becomes perfect before their journey is ended; and the length and minimum diameter of the pipe having been once duly adjusted, the composition of the mixture, when a $2\frac{1}{2}$ inch flame is burning, remains as constant as though the gases had been previously measured and mixed in a holder.

The rate of flow of the gas depends upon the height of the pipe within the reservoir above the surface of the burner, the size of the hole drilled through a plug which blocks the pipe at one point, and the density of the mixed gases. Any three of the four quantities above named being kept constant, the fourth will be constant. Thus the dimensions of the pipe and hole having been fixed, if the density of the gas is constant the rate of flow will be constant; and equally—and this is the principle of the lamp—if the rate of flow is kept constant by setting the height of the flame, the mixture will be the same. It will be seen that the height of the flame furnishes a very delicate test of the rate of flow and of the quality of the gas. For if the gas flows more quickly, the cause must be that it is denser, by having a larger proportion of pentane, and consequently also richer. Both the increased flow and the increased richness make the flame longer. On the other hand, if from any cause the gas entering the pipe is below the standard quality, this will make the flame shorter, both from the causes which operate in the jet photometer, and also because the lower density will diminish the rate at which the gas passes to the burner. The permanent adjustment of the length of pipe and size of hole was made by repeated trials until the flame of the lamp gave exactly as much light as the standard flame. This having been done, similar lamps can readily be produced by measurement.

The height above the surface of the pentane at which the standard gas is to be drawn off varies with the temperature, and therefore needs to be adjusted on each occasion and from time to time. It is convenient to have the means of making this adjustment without exposing the eyes to more light than falls upon them when observing (through a hole in a screen) whether the tip of the flame touches the wire above. The arrangement for this purpose consists of an india-rubber ball filled with water, and connected by a flexible tube with the bottom of the reservoir. By pressing upon the ball with a screw, the water can be raised to any required level in the reservoir; the pentane, supplied drop by drop at about the rate at which it is consumed, floats on the surface of the water. So much heat is absorbed by the evaporation of the pentane that a constant supply of heat is necessary. Such a constant supply is readily obtained by fastening to the reservoir a stout copper wire, which supports a copper disc over the flame. The height and inclination of the disc above the flame may be altered from time to time according to the temperature of the room in which the lamp is used. A glass, T, which connects with the reservoir the supplies of water and of pentane, serves also as a gauge to tell the height of the liquids within the reservoir. A stopcock and bulb beneath the T serve to shut in and keep the small quantity of pentane which is in the reservoir at the end of a testing.

It remains to describe briefly a new form of photometer which has been in use in Oxford for two years. The office of the gas referees has been supplied with one by Mr. Hartley, and Mr. Sugg has been kind enough to send another here to illustrate the present paper. The type is that of Count Rumford's shadow photometer. As in the French system arranged by Foucault, the observer is screened from the direct light of the flames, and looks upon transmitted shadows or half-lights, the chief peculiarity of this arrangement being that the surface which is illuminated by the standard flame is flanked on both sides by similar surfaces illuminated by the more distant gas flame. Through a brass plate in which two similar rectangular slots have been cut at a distance equal to their width, the light from the more distant burner falls on both sides, but not on the centre of a small paper screen, while the light of the nearer standard flame falls only on the centre. It is found that a good judgment can easily be made of the point when the whole of the paper is equally illuminated. For ordinary testing of gas, both burners occupy fixed positions; the standard flame is set at exactly 1ft. from the centre of the screen, and the London argand at 4ft.—the one being 2in., and the other 8in. from a line perpendicular to the screen. The height of the standard flame having been adjusted by looking at its tip only and the wire above through a small opening in the curtain, the tester moves the stopcock, which regulates the supply of coal gas till the illumination of the translucent screen is uniform. He then reads the meter when the minute clock strikes, and again two minutes afterwards. The gain or loss of the meter gives the rate of the gas rather more accurately than a reading after one minute. A table has been constructed on which the corrected illuminating power of the gas can be read off directly by referring to the tabular number, or reading of the aërorthometer at the head of the columns of figures, and finding the line corresponding to the observed gain or loss of the meter in two minutes. No longer description need be given, for an examination of the photometer itself will make its principle and construction clearer than is possible by the fullest account of them.

Three defects in the present system of photometry, apart

* This document is preserved amongst the Davy MSS.

† A paper read before the Gas Institute.

Digitized by Google

from the standard employed, seem to be avoided in the proposed arrangement. First, the placing of the lights to be compared on opposite sides of the illuminated disc raises a difficulty as to the precautions which it is proper to take for the exclusion of extraneous light, or light reflected from the back or sides of the photometer, or, it is said, from the surrounding air. When both lights are on the same side of the illuminated screen, the exclusion of diffused light, whether derived from the sources of light to be compared or elsewhere, is not essential. Darkening of the room in which the photometer stands is desirable only because it makes the eyes more sensitive. Secondly, when the gas has to be regulated to burn at five cubic feet per hour, and the distances have then to be observed at which the two sources of light illuminate the disc equally, two adjustments have to be made where only one is needful. The one condition that, from the nature of the case, must be adjusted at each testing, is the rate at which the gas is to be burnt. In the proposed form of photometer the distances are fixed, and can be verified at any moment by means of a 1-foot and a 4-foot rod; and the only adjustment needing to be made at the time of the testing is that on which the result depends—viz., the adjustment of the rate of the gas so as to produce equal illumination. Thirdly, the London argand, when supplied with less than 5 cubic feet per hour of 16-candle gas, falls off in its yield of light to a degree much greater than corresponds to the falling off in the quantity or quality of the gas, or than a flat-flame burner would show. But a slight falling off in the quality of the gas is not thus exaggerated when this burner is always made to give the light of 16 candles—gas being supplied at the requisite rate. If gas is supplied at sufficient pressure, gas consumers can always get as much light as usual. The way in which they are affected when gas is supplied of lower quality is that they need to burn and pay for more gas. Thus the system to which the new photometer is adapted—of measuring the rate of consumption which yields, with the sample of gas under trial, the light of 16 candles, and inferring thence the illuminating value of the gas—has the advantages of not exaggerating any deficiency in the gas, and of measuring directly that quality of the gas which affects the consumer.

The light of one candle seen in daylight and from a distance appears insignificant; and the remark is frequently made that for measuring powerful sources of light a more powerful standard is desirable. The remark appears to arise from a confusion between light and illumination. Our unit of light is a candle; our unit of illumination should be the illumination caused by one candle at the distance of 1ft. This illumination is as good for the eyes, for reading, or any ordinary purpose, as a stronger illumination; and the eye can judge of this illumination, when comparing one with another, quite as well as of stronger illuminations. If in photometry the disc or standard of light is to move about, and the distance between them be read, 1ft. is rather too short a distance. Small errors of reading or in the working of the apparatus become material. But if the distance is fixed, there is no difficulty in setting a disc or screen and the centre of a burner 1ft. apart with an error not exceeding a few hundredths of an inch; and if a powerful light is to be measured, a moderate-sized room will allow of placing the large burner 20ft. off, which is sufficient for a 400-candle burner. The brilliant light given by the large Siemens burners has been measured in this manner.

ON THE CHEMICAL CORROSION OF CATHODES.*

BY G. GORE, LL.D., F.R.S.

In a paper published in Vol III., p. 36, of the *Proceedings of the Birmingham Philosophical Society*, I stated that "Both common and electro-copper, when used as a cathode, dissolved chemically faster than the same copper without a current;" also that "In the cold liquid† common copper dissolved 2·26 times faster, and electro-copper 2·00 times faster as a cathode than without a current," and "in the hot liquid common copper dissolved chemically 1·39 time faster, and electro-copper 1·07 time faster as a cathode than without a current."

In order to ascertain whether this was a uniform result, I made some experiments of a similar kind with other metals and liquids.

PRELIMINARY EXPERIMENTS.

Experiment 1.—I took twelve similar narrow glass vessels, each containing 3½ ounces by measure of liquid: A and A′ contained a mixture of eight measures of water* and three of pure sulphuric acid; B and B′ six measures of water and one of pure hydrochloric acid; C and C′, two measures of water and one of the same acid; D and D′, the same mixture; E and E′, thirty-two measures of water and one of pure sulphuric acid; F and F′, each containing 3½ ounces of water, and 175 grains of cyanide of potassium.† The metals employed were: For all the anodes, except that in F, sheets of platinum, and for that in F a sheet of steel; I also took for a cathode and comparison sheet two perfectly similar pieces, one inch wide,‡ of the same metal for each liquid; for A and A′ two pieces cut from the same sheet of rolled nickel known as "Fleitmann's," containing a small proportion of zinc alloyed with it to render it ductile; for B and B′, similar to those in A and A′; for C and C′, two sheets of extremely pure tin, cut from the same piece; for D and D′, two sheets of electro-deposited copper cut from the same piece; for E and E′ two sheets of highly carbonised steel cut from the same piece;§ and for F and F′ two sheets of pure silver cut from the same piece. All the cathodes and comparison sheets were perfectly cleaned, then weighed, and immersed at the same time in a vertical position, and to the same depth (usually 2¼in.) in their respective liquids; and the latter were all maintained at the atmospheric temperature (about 16° C.) during the whole of the experiment. The electric current employed was from a series of four Smee cells, and was passed through the six vessels in single series, the current commencing from the time of immersion of the metals. The two pieces of steel and their vessels E and E′ were removed from the series at the end of seven hours in consequence of greater rapidity of corrosion. The cathodes and comparison sheets of tin, copper, and silver in vessels C and C′, D and E′, and in F and F′, were removed at the end of twenty-four hours, and those of nickel in vessels A and A′ and B and B′ were removed after thirty hours of action. No gas was visible upon the copper in D during the experiment. The following are the losses suffered by the several cathodes, and the corresponding comparison sheets:—

		Losses in Grains.
A	Nickel cathode in dilute sulphuric acid ...	·077
A′	„ comparison sheet „	·092
Proportion of loss, 85·7 to 100 = a protective effect of 16·3 per cent.		
B	Nickel cathode in dilute hydrochloric acid.	·157
B′	„ comparison sheet „	·197
Proportion of loss, 79·69 to 100 = a protective effect of 20·31 per cent.		
C	Tin cathode in dilute hydrochloric acid ...	5·441
C′	„ comparison sheet „	4·793
Proportion of loss, 113·5 to 100 = a corrosive effect of 13·5 per cent.		
D	Copper cathode in dilute hydrochloric acid	·465
D′	„ comparison sheet „	·202
Proportion of loss, 230·2 to 100 = a corrosive effect of 130·2 per cent.		

* From the *Proceedings of the Birmingham Philosophical Society*.

† The "liquid" was "a mixture of ten volumes of distilled water and three of pure sulphuric acid."

* Distilled water was used in all cases.

† This sample of cyanide was found by analysis to contain 86·65 per cent. of actual cyanide. Samples of the purest commercial cyanide of potassium appear to contain traces of sulphide, probably derived from sulphate deoxidised during the process of fusion.

‡ All the cathodes and comparison sheets were one inch wide. This width of electrode was used in all subsequent experiments, unless otherwise stated.

§ The comparison sheet of these two had been heated to redness before the trial, and this may have effected the speed of corrosion.

Digitized by Google

	Losses in Grains.
E Steel cathode in dilute sulphuric acid	2·550
E′ „ comparison sheet „	4·050

Proportion of loss, 62·96 to 100 = a protective effect of 37·04 per cent.

F Silver cathode in a solution of potassic cyanide	1·815
F′ Silver comparison sheet of potassic cyanide	1·832

Proportion of loss, 99·06 to 100 = a protective effect of ·94 per cent.

Remarks and Conclusions.—The results in these preliminary experiments indicate that in some cases the chemical corrosion of a metal is increased, and in others decreased, by making the metal a cathode. Other causes, such as capillary action, minute differences in the surfaces of the plates, &c., however, operate.

Experiment 2.—Two sheets of nickel were again compared in a mixture of equal measures of hydrochloric acid and water; and two of tin were also compared in a mixture of one volume of hydrochloric acid and 1½ volume of water, a current from two Smee cells being passed into the nickel cathode, and a separate similar current passed through the tin one, each during 16 hours. The nickel cathode was then covered with a thin film of black powder, and gas was rising from its surface; the comparison sheet exhibited similar phenomena, but only in a very minute degree. The sheets of tin also were covered with minute adhering bubbles of gas; larger in quantity upon the cathode than upon the comparison sheet. After removal of adhering powders

The nickel cathode had lost	1·489 grain.
„ „ comparison sheet had lost...	·172 „

Proportion of loss, 865·7 to 100 = a corrosive effect of 765·7 per cent.

The tin cathode had lost	2·500 grains.
„ comparison sheet had lost	2·810 „

Proportion of loss, 88·96 to 100 = a protective effect of 11·04 per cent.

Remarks and Conclusions.—On comparing the results with those obtained with the same metals in Experiment 1, we find that with a somewhat less dilute acid the effects with tin were reversed, also that with a much stronger mixture of acid, and a stronger electric current, instead of the nickel cathode being somewhat less corroded than the comparison sheet, it was corroded 8·6 times as much. This might in chief part be accounted for by the liberation of gas and electrolysis of the liquid stirring up the solution, and somewhat by liberated solid impurity causing local action.

It is manifest that if gas is set free at the surface of the plates, and remains adhering to them, it must diminish the amount of corrosion, and that if it rises to the surface it must move the liquid and bring fresh particles of it into contact with the plate and increase the corrosion. These effects of ordinary chemical action are of course liable to occur both in the current cell and in the comparison one; and, in addition, gas may also be evolved by electrolysis in the current cell, and thus alter, either by increasing or decreasing, the amount of such corrosion. It is manifest also that any impurity in the metal must affect the results in several ways, which may differ with the nature of the impurity. If the material were an insoluble solid it would be liberated and adhere to the metallic surface, and if it were electro-negative it would form with the metal a voltaic couple and increase the corrosion, and each of these circumstances must be taken into account. The loss of weight by removal of the insoluble matter is also an element in the case, but with nickel in dilute hydrochloric acid that amount was small. An electric current may increase the corrosion of a cathode by depositing upon it a film of any less positive metal which may happen to be present as a soluble impurity, and this may account for the great acceleration of corrosion of the nickel cathode; it might also account for some of the variations in the effect of the current with copper.

The foregoing and the following experiments show that the loss of weight of a cathode in an electrolyte is dependent upon several conditions, such as difference of metal, of liquid, or of strength of liquid, some of which tend to increase, and others to decrease the corrosion.

No further experiments were made with nickel, in consequence of its impurity.

Experiment 3.—Two perfectly similar sheets of iron were compared in two portions of a mixture of one volume of hydrochloric acid and seventy-two volumes of water, a current from two Smee cells being employed, and the experiment continued 6½ hours. Both sheets evolved a very small amount of gas, but remained clean and bright.

The cathode lost	·305 grain.
The comparison sheet lost	·480 „

Proportion of loss, 62·5 to 100 = a protective effect of 37·5 per cent.

Remarks.—The cathode lost the least. This result agrees with that obtained with steel in dilute sulphuric acid, and the proportion of loss of cathode to comparison sheet was about the same in each case.

Experiment 4.—The same two sheets of copper used in Experiment 1 were now compared in a mixture of two measures of hydrochloric acid and one of water, with a current from two Smee cells, continued 19½ hours. A few small bubbles of gas appeared on the cathode. Both portions of liquid became yellow, but the electrolyte the most so, probably in consequence of liberation of chlorine by electrolysis.

The cathode lost	·114 grain.
The comparison sheet lost	·535 „

Proportion of loss, 21·3 to 100 = a protective effect of 78·7 per cent.

Remarks and Conclusions.—In this case the comparison sheet was much the most corroded. The result is opposite to that obtained with the same pieces of copper in a mixture of two volumes of water and one of hydrocheric acid, in Experiment 1.

Experiment 5.—The object of this experiment was to compare with the last one for influence of difference of strength of electric current. The copper plates were as similar as possible to those used in that instance. The acid mixture was also of the same strength. The current was from a single cell, and continued 19½ hours.

The cathode lost	·495 grain.
The comparison sheet lost	·521 „

Proportion of loss, 95·15 to 100 = a protective effect of 4·85 per cent.

Remarks and Conclusions.—In this case also the comparison sheet was (though to a small extent only) the most corroded. The stronger current in the previous experiment appeared to have a greater effect in diminishing the chemical corrosion.

The following experiment is a usual example of the behaviour of a silver cathode in a solution of potassic cyanide.

Experiment 6.—Two plates of pure silver one inch wide and four inches long were immersed 2½ inches deep, each in separate portions of three ounces of water containing 300 grains of potassic cyanide (sample "a"); and a current from two Smee cells passed through one of the portions by means of an anode of sheet iron* of similar dimensions and amount of immersed surface. No gas was perceptibly evolved, or silver deposited. After 22½ hours' action at the atmospheric temperature,

	Grains.	Grain.
The cathode had lost	·759 =	·0337 per hour.
„ comparison sheet had lost...	2·210 =	·0977 „

Proportion of loss, 34·34 to 100 = a protective influence of 65·66 per cent.

The electrolyte now contained ·759 grains of dissolved silver.
The comparison liquid now „ 2·210 „ „ „

Remarks and Conclusions.—The current protected in a conspicuous degree the cathode from corrosion, without at the same time depositing any silver. The results also show that

* Anodes of iron were alone used in solutions of potassic cyanide until it was found that they slightly dissolved; platinum ones were subsequently employed.

Digitized by Google

the electric current from two Smee elements does not deposit silver upon a cathode exposing $2\frac{1}{2}$ square inches of front surface from a liquid containing ·759 grain of silver dissolved in a solution of 300 grains of cyanide of potassium of 86·65 per cent. and three ounces of water. From the sufficient continuance of the experiment, the small amount of silver dissolved from the cathode in comparison with the much larger amount dissolved from the comparison sheet, it is very probable that the conditions of the electrolyte and current had arrived at what may be termed a "balanced" state—*i.e.*, a state in which metal is neither dissolved from, nor deposited upon, the cathode.

Want of uniformity of result was usually greater with other metals than with silver, probably in consequence of the metals being less pure and more easily oxidised ; tin might perhaps prove an exception to this.

INFLUENCE OF STRENGTH OF ACID.

Experiment 7.—To ascertain the influence of the strength of hydrochloric acid, a mixture of one volume of water and two of that acid was put into one glass, and two volumes of water and one of the acid in a second glass. Each glass also contained an anode of platinum and a cathode of electro copper one inch wide, immersed $2\frac{3}{8}$in. in the liquid. The two vessels were connected in series, and the current from four cells passed through them during $19\frac{1}{2}$ hours. Two other glasses contained similar liquids and metal plates for comparison. The following were the alterations in weight:—

Stronger Mixture.

The cathode gained	·002 grain.
The comparison sheet lost	·283 „

Weaker Mixture.

The cathode lost	·003 grain.
The comparison sheet lost	·227 „

Remarks and Conclusions.—The strong current diminished the amount of corrosion greatly in both cases, and most in the stronger mixture.

Experiment 8.—The influence of strength of sulphuric acid was also tested with three copper cathodes (and platinum anodes) in three glasses in single series. The first glass contained a mixture of one volume of sulphuric acid and two of water; the second, one volume of that acid and twenty of water; and the third, one volume of acid and forty of water. The current from four Smee cells, in single series, was passed through the vessels during eighteen hours. Three separate glasses contained similar mixtures and comparison plates. The following were the alterations of weight:—

	Grain.
Cathode in 1 vol. of acid and 2 of water lost..	·045
Comparison sheet „ „ „	·062

Proportion of loss, 72·6 to 100 = a protective effect of 27·4 per cent.

Cathode in 1 vol. of acid and 20 of water lost	·123
Comparison sheet „ „ „	·121

Proportion of loss, 101·65 to 100 = a corrosive effect of 1·65 per cent.

Cathode in 1 vol. of acid and 40 of water lost	·093
Comparison sheet „ „ „	·120

Proportion of loss, 77·5 to 100 = a protective effect of 22·5 per cent.

Remarks.—By comparing these results with the ones obtained with copper in dilute hydrochloric acid, it appears that the influence of the current upon the corrosive action is much greater in dilute hydrochloric acid than in dilute sulphuric acid.

The considerable variations in the results indicate that several influences operate to affect the rate of corrosion, and that it would require an extensive research in order to determine even in a few cases what the proportions are in which those influences participate indroducing the effect.

INFLUENCE OF CAPILLARY ACTION.

One of the circumstances which affected the corrosion was capillary action, a description of which is contained in another paper on "The Electrolytic Balance of Chemical Corrosion."

UNEQUAL CORRODIBILITY OF THE METAL.

Another circumstance which disturbed all the results was the extreme difficulty of obtaining pieces of metal which corroded equally. The following experiments illustrate this :—

Experiment 9.—Two pieces, A and B, each $2\frac{1}{4}$in. long and 1in. wide, were cut from contiguous parts of a sheet of pure silver, then cleaned very carefully and immersed at the same time to an equal depth—$2\frac{3}{8}$in.—nearly vertically, in a single portion of a solution of 75 grains of potassic cyanide (sample "a") in three ounces of water, during fifteen hours at atmospheric temperature

Plate A lost	·992 = ·0661	grain per hour.
Plate B lost	1·698 = ·1132	„ „
Difference	·706 = ·047	„ „

After a second immersion during five hours

Plate A lost	·645 = ·1290	grain per hour.
Plate B lost	·691 = ·1382	„ „
Difference	·046 = ·0092	„ „

After a third immersion during three hours

Plate A lost	·357 = ·1190	grain per hour.
Plate B lost	·385 = ·1283	„ „
Difference	·028 = ·0093	„ „

Remarks.—The difference of rate of corrosion, which was great at first, diminished considerably in the case of re-immersion. The influence of the difference of rate of ordinary chemical corrosion under apparently the same conditions affected more or less the whole of the results of this research, and was largely unavoidable.

(TO BE CONTINUED.)

THE EASTERN TELEGRAPH COMPANY (LIMITED).

The twenty-second half-yearly general meeting of this Company was held on the 12th inst., at the Cannon-street Hotel, under the presidency of John Pender, Esq., M.P.

The SECRETARY (Mr. George Draper) read the notice convening the meeting and the minutes of the last meeting, which were confirmed by the present one. The report of the directors, of which an abstract has appeared in *The Electrician*, was taken as read.

The CHAIRMAN said that the revenue for the past six months to the 31st March last had been £328,404, being an increase of £6,595 over the corresponding period of 1882. To earn this increased amount of money, it was necessary to keep open the communications with Egypt at any cost. On this exceptional account they spent over £62,000, employing no less than six ships. Some of the expenses were charged against the September half year, but many of the items they incurred before the September half appeared in the present account. Everything had now been charged, and he thought the result must be considered very satisfactory. The South African Company, of which this Company held almost all the shares, paid them 8 per cent., as compared with 10 per cent., the reduction being owing to the cessation of hostilities. He trusted that they would grow from the 8 per cent. in future through the commercial prosperity of the country, and not through the operations of war. The ordinary expenses of the Company had been £87,827, being an increase of £12,686. After going through the items, and stating that the increase was not of a permanent nature, he observed that the working expenses at the stations also showed an increase of £8,863, owing to the opening of six new stations. After meeting all the additional charges, they were enabled to pay a dividend and bonus together equal to 6 per cent. for the year, as compared with $5\frac{1}{2}$ per cent., and also to carry £85,000 to the general reserve fund, as compared with £75,000 in 1882. The undoubted services which they had rendered to the Government in connection with the war in Egypt had given them a most important position, not only with the British Government, but with other Governments. The consequence of this had been that they had been approached by the French Government, who were engaged in a war in the far East, and who saw the advantage of the services rendered by the Company in the Egyptian expedition, with the result that he believed at the present moment a convention was signed by the French Government enabling the telegraph system to be carried from Saigon to Tonquin. That would be an additional feeder to their system. Since their last meeting they had also laid down a triplicate line in the Red Sea from Suez to Aden, which would prevent any further complaint from the Cape people. He congratulated them on the fact (which he had not been able to do since 1879) that they had not at the present moment one of their ships employed, all their cables being in good working order. The line which they had laid along the Suez Canal through an arrangement they made with the Suez Canal Company had only been opened about twenty-four hours when the Eastern Company's landline through Egypt was run into by a railway train, and, but for this new line, which was only opened in the nick of time, they would have had a very serious loss. He thought that the Company might claim to be a very important factor in the great success which had attended the Suez Canal, for the submarine telegraph was almost the beginning of every operation that took place in the East

Digitized by Google

and he might almost say the end of the operation also. He had often spoken of a submarine cable being a very speculative property, but seventeen years experience had satisfied them that it was about as good a property as railway property, for they knew where a break occurred and could repair it. He therefore thought that the debenture stock which they were offering to the public was to be regarded as a thoroughly safe and sound investment. The stock would be required for redeeming debentures falling due next October, and in connection with other capital purposes. He concluded by moving the adoption of the report, the payment of the preference dividend, and the payment of the dividend and bonus recommended on the ordinary shares.

The VICE-CHAIRMAN (the Marquis of Tweeddale) having seconded the motion, it was carried unanimously.

The CHAIRMAN, in reply to Mr. Fisher, stated that the Company was now earning £400,000 a year net, and that the interest on the debenture stock which they were offering for public application was only £20,000. Having regard to the ease with which they could repair their cables, and to the fact that they had nearly £570,000 reserve fund, he repeated that the new debenture stock might be regarded with the utmost favour.

On the motion of Mr. JOHN NEWTON, a vote of thanks was passed to to the chairman and directors, and in reply,

The CHAIRMAN referred to the growing importance of submarine telegraphy, and expressed sympathy with Mr. Newton's remarks as to the amount of the dividend. If they had had open messages, as was expected at first, they would have been paying 60 per cent. instead of six per cent.; but the fact was that they had been beaten by the ingenuity of the merchants in the coding system.

The proceedings then terminated.

[We shall publish a *verbatim* report of this meeting in our next issue].

THE WEST COAST OF AMERICA TELEGRAPH COMPANY, LIMITED.

Report of the directors to be submitted to the sixth ordinary general meeting to be held on July 19th, 1883:—

The directors have to present to the shareholders the annexed accounts for the year ending the 31st December, 1882, showing the gross revenue to be £38,908 2s. 10d., against the sum of £32,356 15. 11d. for the previous year, and leaving a nett balance of profit, after paying debenture interest, of £7,667 11s. 1d.—a result, which, though not altogether satisfactory, is yet far from unpromising, regard being still had to the continuance of active hostilities on the West Coast, and to the utter paralysation of trade at Lima and elsewhere in Peru. Since the 31st December last, the date up to which the balance-sheet is made out, the Board are, however, pleased to state, a considerable improvement has taken place in the position and prospects of the Company. The mortgage upon the Company's steamer, and all the other liabilities and arrears of the Company, set down at £20,465 8s. 5d. in the Company's balance-sheet for the year 1881, have been discharged and extinguished, and the shareholders may now be congratulated on the Company being at length a dividend-earning concern. Without counting upon any increase of business which may be reasonably looked for from the conclusion of peace, and the improved condition of affairs on the West Coast, the gross average earnings for the past six months point to an aggregate income for the current year of more than £50,000—a sum sufficient, as will be seen on reference to the figures in the balance-sheet, not only to meet all the current engagements of the Company, but to form an adequate reserve, and also to pay a dividend on the ordinary shares. Instead of this income decreasing there seems to be every prospect of its increasing; whilst the Company's expenditure will, it is hoped, show at the end of the year a diminution rather than an increase. In view of the improving position and prospects of the Company, and also in view of the meetings of the Company being held only once a year, it is intended to submit a resolution, and take power, which can only be given by a general meeting, to declare interim dividends—subject to the formation of an adequate reserve—out of such profits as may be from time to time justly available. The claim of this Company upon the Chilian Government is still unsettled, but the Board have unabated confidence in ultimately obtaining from the Government a reasonable and honourable settlement. An important step has been gained in this direction by the institution in Chili of an International Commission, constituted to adjudicate upon claims arising out of the conflict between Chili and Peru. This tribunal, under the terms of its appointment, is happily bound to adjudicate upon all claims within a specified time. A satisfactory arrangement has been made by the Board with the Central and South American Telegraph Company, for the joint employment on the coast of this Company's repairing steamer. The new through route from England, and from the whole of Europe, viâ Galveston, extending to the entire coast of South America, is now attracting business by its expeditious and satisfactory working, the electrical condition and general efficiency of the cables leaving nothing to be desired. The members of the Board retiring by rotation are Mr. Thomas Fielden Campbell and Mr. W. E. M'Andrew, both of whom, being eligible, offer themselves for re-election. The auditor, Mr. J. Weise, of Messrs. Turquand, Youngs, and Co,, retires, and is eligible for re-election.

TURKISH PATENTS.

NOTICE TO PATENT AGENTS AND INVENTORS.

The undersigned having established a special agency in Constantinople, are prepared to SECURE PATENTS in TURKEY for all inventions not yet in use in that country for £35, including drawings of average amount.

Special terms to Patent Agents.

W. P. THOMPSON and CO.,
BRITISH and INTERNATIONAL PATENT AGENTS,
6, LORD-STREET, LIVERPOOL
(and 323, HIGH HOLBORN, LONDON).

A TELEGRAPH ENGINEER will shortly require a RE-ENGAGEMENT as MANAGER of Cable and General Insulated Wi o Works. Gutta Percha and India Rubber Core; Military, Torpedo, Electric Light Cables and Leads; I.R. Cut Sheets, &c.; G.P. Surgical and other Sheets, &c.; Spreading. Sixteen years' experience in principal firms. Can provide complete instructing staff, mechanical and electrical. Terms inclusive. Any part of Europe. Address, in first instance,
"G. P.," care of Harding, Cocks, and Co.,
29, Jewry-street, Fenchurch-street, London.

WANTED, TWO or THREE (or more) GERMAN WORKMEN or STUDENTS to join with advertiser in any part of London in READING DYNAMO MACHINE LITERATURE. No expenses.—Address J. W., 21, Herbert-street, New North-road, N.

WANTED, RE-ENGAGEMENT as SUPERINTENDENT or Manager of Electrical Work. Advertiser has had extensive experience in all the principal dynamos and electric lighting, also their construction, as well as that of engines. Has held a similar position. Can speak four European languages, and has no objection to go abroad. Address, "K. N.," ELECTRICIAN Office, 396, Strand, W.C.

TO BE SOLD, A GREAT BARGAIN. 2 A GRAMME DYNAMOS. Equal to new. Only been running a fortnight for experimental work. Apply to JOSEPH RICHMOND and Co., 31 and 32, Kirby-street, Hatton-garden, E.C.

A GENTLEMAN is desirous of REPRESENTING in LONDON Manufacturers of Electrical Appliances and Material, on salary or commission. Address, "Erg," Office of THE ELECTRICIAN.

DYNAMO to light Fifty 20 c.-p. Swan Lamps, £40; ditto to light Twelve, £20; to light Six 15 c.-p., £8.—OPPERMANN BROS., Brewhouse-yard, 172, St. John's-street, E.C.

Just published, crown 8vo., cloth, 154 pp., with 62 Illustrations, price 4s. 6d.,

PRACTICAL ELECTRIC LIGHTING. By A. BROMLEY HOLMES, Assoc. M. Inst. C.E., containing Explanations of the Principles on which Electric Lighting Apparatus is Constructed. Descriptions of machines, lamps, secondary batteries, &c. Particulars of prime cost and cost of maintenance. Practical directions for working the light, &c.

London: E. and F. N. SPON, 16, Charing-cross.

NOTES.

Telegrams for South Africa.—The cable between Zanzibar and Mozambique is repaired.

Telegrams for China.—Telegraphic communication has been opened with Canton and Foochow.

Society of Arts.—The *conversazione* of this society is to be held at the Fisheries Exhibition on Wednesday next, July 25th.

South Africa.—The cable between Mozambique and Zanzibar is now repaired, and telegraphic communication with South Africa restored.

The Metropolitan Board of Works.—We understand that the petitions of the Board against the electric light orders have been withdrawn.

The Provisional Orders.—The Board of Works for the Westminster district have resolved to oppose electric light schemes affecting their district.

Use of Primary Batteries.—Messrs. Laing, Wharton, and Co. have temporarily lighted a bazaar at Lewisham with Swan 10 candle-power lamps, obtaining the current from Emmens's primary battery.

Prof. Forbes's Accumulator.—The Electrical Carbon, Storage, &c., Company of Scotland are issuing price lists for this battery. They give the E.M.F. at 2·5 volts, as against 2·25 volts of most other batteries. We fancy 2·25 volts is a rather high E.M.F., except in the initial stage of discharge.

The ss. "Gabo."—In consequence of the great satisfaction given by the electric light on the ss. "Berwick," the Electric Carbon Storage and Apparatus Manufactory Company, of Scotland, have received instructions to light up the ss. "Gabo," for Melbourne. One hundred incandescent lamps and two arc lamps will be used in this installation, Higgs's self-regulating dynamo machine being again employed.

The India Rubber, Gutta Percha, and Telegraph Works Company.—The half-yearly general meeting of this company will be held at the Cannon-street Hotel on Tuesday, the 24th instant, at 12 o'clock noon, for the purpose of obtaining the sanction of the shareholders to the payment of an interim dividend. The business of the company for the past half year has been satisfactory, and the directors will, at the meeting, recommend the distribution of an interim dividend of 5 per cent., or 10s. per share, free of income-tax.

Thunderstorms on the Continent.—On Friday evening last week a thunderstorm which burst over Geneva traversed the Jura, and the lightning set on fire the schoolhouse of Villers, in French territory. The children, forty-five in number, were half suffocated, and rendered so helpless that the master had to carry them out one by one. The last was rescued only a few minutes before the building was enveloped in flames.—A similar tragedy is reported from the village of Sotmar, near Brunswick. During a thunderstorm a mother and her four children, to whom she was reading, were killed by a single flash of lightning. Two other children who were close by were uninjured.—A severe thunderstorm, accompanied by waterspouts and hail, occurred in Silesia on Monday last, and caused serious damage. A paper manufactory at Eylau was struck by lightning and burnt down.

Electric Lighting at Walham Green.—The Butchers' annual fête, held on Tuesday, July 17th, at the Almshouses, Walham Green, was lighted by five Crompton arc lamps of 4,000 candle-power each, supplied with current by two Bürgin machines driven by a portable steam engine. Messrs. R. E. Crompton and Co. have lighted this fête for the last four years very successfully, but until this year fewer lights were used, and the large marquee in which the ball is held was lighted with candles. The committee, however, being so well pleased with the former lighting of the grounds, determined to use electricity inside the ball tent, and therefore instructed the contractors, through their indefatigable chairman, Mr. Calcutt, to fix two arc lamps in place of the candelebras usually containing a large number of candles. The effect of the lighting both inside and out was very fine, and gave great satisfaction.

Sixpenny Telegrams.—In reference to sixpenny telegrams, says the *Echo*, it may be noted that at the last preliminary examination held by the Civil Service Commissioners for male telegraph learners, nearly thirteen hundred candidates presented themselves. They will all be wanted if the sixpenny rate is adopted, but unfortunately it takes many months to train an operator, and a very large percentage of candidates fail when the test of practical work is tried. Any fifth standard Board School boy can easily pass the preliminary examination; but the actual work of the telegraph requires special faculties, and those may be found highly developed in lads who are not otherwise so bright as their competitors. At any rate, the telegraph service offers quite as profitable a field as the majority of trades, and is worth the attention of parents who, having sons and daughters, are at a loss for an occupation for them.

The Edison Electric Light.—The Criterion Theatre, Piccadilly, is to be lighted throughout with about 600 Edison incandescent lamps. The generating plant will comprise two Armington and Sims horizontal high-speed engines, having 13in. cylinder by 13in. stroke, running at 275 revolutions per minute, and driving on to countershafting from which will be run four Edison *l* dynamos each capable of sustaining 150 sixteen-candle lamps. Each engine will be capable of indicating eighty-four horse-power at 70lb. pressure, and either engine will thus be able to take the whole load in the event of accident or repairs to the other. The wiring will be arranged on eight circuits, each under independent control, by means of a specially designed regulator capable of lowering or raising the brilliancy of the lamps from normal candle-power to *nil*. The contract for the work, which will be carried out by the Edison Electric Light Company, stipulates for the completion of the installation by the beginning of September.

Sheepish.—The intelligence of the press on technical matters in this country is on a par with that of a baby on soft soap. As soon as an exhibition opens the various papers commence to "report," but the peculiarity remains that the same errors run through scores of reports. One such error in matters electrical is now going the round of the press. We could, if we chose, point out the paper in which the error was made, but it would be impossible to point out the score or so of papers who have faithfully copied the error. Is the Leeds Forge Company's exhibit at the Metal Trades Exhibition lighted by a "storage," or by a primary battery? The papers say it is from a storage battery, and is as successful as it is pleasing in effect, and the result shows the progress made towards independent house lighting from storage batteries. We shall be glad to hear of the firm that claims this storage battery. The lighting may be successful, may be pleasing, may, indeed, be perfect, but whose is the storage battery? We are prepared to maintain, and we think we can prove, that not 5 per cent. of those who report exhibitions ever see the exhibits.

Stalybridge.—At a late meeting of the Stalybridge Town Council, in moving the confirmation of the minutes of

Digitized by Google

the Finance Committee, reference was made to an item of £10 odd which appeared in the accounts as the expenses of opposing an Electric Lighting Bill in Parliament. It was thought unfair that any company could put them to the expense of opposing their Bills. In this instance the company brought forward a Bill which was illegal, and after a time it was withdrawn. This year the company had again applied for powers. It is something of a scandal that two or three electric lighting companies can put corporations to expense, and that, when the corporation opposed the Bills and won the case, no costs could be obtained. Every corporation in England is interested in the matter, for all were liable to be put to expenses of this kind. It was a hardship upon the ratepayers that adventurers could form companies, come and frighten corporations, and make them pay into the bargain. It was believed that in many instances these Bills were got up by the score. Printed copies were sent round to corporations, who were put to the expense of opposing. Then, when powers were got, they were simply sold for pounds, shillings, and pence, and companies were making dividends by selling privileges which they got from Parliament for nothing, while corporations were bearing the expense of opposing.

The Telegraph in Journalism.—In an address on "Journalism," delivered by Mr. Charles Emory Smith, at Lafayette College a few days ago, the speaker referred to the part played by the telegraph in the development of modern journalism, and said: "A number of journals now have their own special wires from leading points. The time will soon come when, apart from their ordinary news-gatherers, they will keep the ablest men they can find constantly at the capitals to deal critically with the operations and the legislation of the hour; when the editorial comments will be written on the scene, with all the colour and life and intelligence of actual presence; when they will be put upon the wires as freely as the general news—nay, further, the time is near at hand when the keenest and most experienced observer, waiting till the last moment for the freshest phases in the kaleidoscopic changes, will stand at the telephone in Washington and talk his clear, well-digested comment; when it will be simultaneously received in the newspaper office in Philadelphia, instantly converted by the type-writer into printed copy, and immediately passed on to the composing room. In short, when the carefully gathered information of the acutest journalist spoken in Washington at one o'clock in the morning over the wire will be all ready at two o'clock in Philadelphia to be-rattled off the printing press at the rate of fifty thousand an hour."

Expected Strike of Telegraph Operators in America.—According to a telegram received by the *Daily News* from its New York correspondent on Tuesday, a committee of telegraphers, professing to represent fifteen thousand operators, formally presented the demands of the association to the Western Union Company, and requested a general increase of 15 per cent. in the salaries, and a reduction of one hour in the day's work. No time for the reply was stipulated for, and no threats were made. A general strike within a few days is imminent. According to the *Standard* of same date, the strike of telegraph operators is extending and threatens to stop the entire service in the States. The Direct Atlantic Cable and the French Cable Companies are not affected by this suspension of work. The object of the clerks is to obtain better hours and equal pay for the same amount of work, whether it is done by men or by women. The men fear lest their rate of pay should be reduced to the same scale as the women's. The organisation of the operators is strong, but the companies declare that they are prepared to meet it. The Operators' Committee have formally requested an advance in wages of fifteen per cent., and a reduction of the hours of work from nine to eight. No answer has yet been given. Telegraphing on Tuesday the *Standard's* correspondent says "The telegraph operators on strike are confident of success; the company is determined to defeat them." On Wednesday the same correspondent telegraphs that the Western Union Company, without directly answering the operators' delegates, has appointed a committee to consider the complaints of the servants. This is regarded as an evasive step, and a strike is still possible.

Legal.—In the Queen's Bench Division of the High Court, on Thursday, Mr. Justice Lopes and Mr. Justice Williams, sitting in banco, had before them the case of "The Central News *v.* the Eastern Telegraph Company and the Exchange Telegraph Company," an action brought for alleged divulging of telegrams sent from the plaintiffs' agent at Kassassin by the Eastern Company's wires during the war in Egypt. The case did not come before their lordships on its merits, but merely on the question of allowing the plaintiffs' agent, Mr. Burleigh, the plaintiff's special correspondent at Kassassin, to be present during the examination of witnesses by commission, preparatory to proceeding with the action—these being some telegraph clerks now home temporarily from foreign stations.—Mr. Finlay, Q.C., with whom was Mr. Moulton, as counsel for the defendants, remarked, however, that these preliminary proceedings were in the nature of "a full-dress rehearsal," being an inquisition with the object of making out a case against his clients. The defendants objected to the presence of Mr. Burleigh during the examination of these witnesses, on the ground that he was a director and shareholder of the plaintiffs' company, and a principal witness for the plaintiffs in the cause.—Mr. A. M. Sullivan, who appeared as counsel for the plaintiffs, submitted that the objections of the defendants were not substantial, and stated that the examiner himself had expressed the opinion that Mr. Burleigh ought to be present during the examination, although he had referred the matter to the Court in order to avoid any dispute on the point hereafter. Having heard counsel, the Court decided that Mr. Burleigh ought to be present.

A Compromise.—A foreign paper devoted to gas-lighting interests announces an invention which promises to bring the two rivals, gas and electricity, into close partnership. Through an ordinary gas flame a curved metallic rod is passed, the said rod consisting apparently of platinum, though this is not very clearly stated. A slight current of electricity, such as would be supplied by one or two small elements, passed through this rod will be found, it is said, immensely to increase the illuminating power of the gas flame. A light four or five times as great as that of the unassisted flame, and at a cost of one-third, is the result announced, though as to all such calculations it really seems to be of little use to take any notice of them when inventors and their friends trot out their little bantlings; but if it should prove to be the fact —and the statement is one which any electrician may put to immediate test, and would hardly, therefore, have been put forward without some degree of truth—that a slight current passed through a platinum wire will affect a gas flame as asserted, it may have very important results in connection with domestic arrangements for lighting and heating. The relative proportion of luminous and heat rays is completely altered, it is affirmed, and the arrangement is capable of furnishing "all gradations, from the brilliant flame to the most calorific radiations." It is very well known that a gas for heating purposes only could be supplied to housekeepers at a

Digitized by Google

much lower rate than for lighting, and, if this invention should be capable of acting as it professes, it seems very possible that a gas supply of the cheaper description, adapted for heating alone, may by the co-operation of the electric current be converted instantly into an illuminating agent. In the interests of consumers, therefore, it is to be hoped that this reported invention is genuine.—*Globe*.

INTERNATIONAL ELECTRICAL EXHIBITION, VIENNA.—According to official information the following states, besides those previously mentioned, will be represented at this exhibition by delegates:—Belgium will send the engineer, Mr. Evrard, who has been likewise entrusted with the organisation of the official Belgium section, together with Messrs. Rau and H. Witmeur. Roumania will officially send Professor Bacaloglu and Captain Michel Boteanu for studying the exhibition. From Russia will come the general telegraph instructor, Mr. Pissarewsky and Mr. Tiedemann, sent by the general direction of the Imperial Russian Telegraphs as delegates. Mr. Ph. Welitschko, president of the commission, also attends for Russia. The commission has been formed by command of the Russian Emperor for the organisation of a Russian section. The Imperial Russian Polytechnical Society will send as delegates Messrs. Oreste Darislowitch Chivolson, Doctor of Physics, and Colonel Wead Takowlewitch Florensoff, Professor of Chemistry at the Cavalry School of the Emperor Nicholas; as chief commissionary of the Russian section, Mr. T. L. Crestin, engineer at the Public Cartridge Factory; as commissaries, the electrician, Mr. A. N. Ladriguine, and the Professsor of Physics, Mr. Jacques T. Kowalsky, and finally as deputy commissaries, Colonel Michel A. Saline, Professor of Mathematics in the Imperial Corps of Porges; Mr. Michel M. Dochenoff, mine engineer; and Mr. Serge Nikolajiwitch Stignanoff, electrician and editor of the Russian journal, *The Electricity*. From Turkey the general post and telegraph director, Mr. Izzet Effendi, who has been ordered by the Turkish Government to organise the Turkish section, has nominated as delegates for the exhibition the president of the Technical Bureaus, Mr. Emile Effendi Lacoine and his colleague Mr. Raif Effendi.

MR. EDISON AND ELECTRIC RAILWAYS.—Commenting on the reported interview with the great inventor which we mentioned in our last, the *Echo* remarks "Mr. Edison has been 'interviewed' recently on the subject of electric railways, and as he probably had no objection to undergo the operation, there is possibly some substratum of fact in the reports published; but it will be news to many to learn that he is building an electric locomotive of 375 indicated horse-power and six-foot driving wheels, which is to be used on the Underground Railway in London, 'where smoke and vapours are very offensive.' This engine is to haul from eight to ten passenger coaches at a high rate of speed, from forty to fifty miles an hour; and as Mr. Edison promises to make it perform what he has undertaken, it is to be hoped that the pioneer engine will soon be on its road. Mr. Edison, however, does not think that electricity will be generally adopted for heavy trains or over long distances, but he and his partner, Field, have many applications for the use of their patents—the motor of the future being, in Mr. Edison's opinion, of one the designs patented by Mr. Field. Although steam will eventually be superseded by electricity as a motive power, in Mr. Edison's opinion, he does not think the change will be effected just yet; but, as a climax, he expressed another belief, that, sooner or later, means will be found to obtain electricity from the earth without any machinery whatever. Happy days those for everybody; but we expect the electric locomotive on the Underground will arrive long before electricity to work it is obtained from the earth, except in the shape of that other form of energy commonly called coal. For the sake of Mr. Edison's reputation, it is to be hoped that the interviewer has misunderstood him, for the idea of drawing electricity from the earth has neither the merit of novelty nor the probability of dethroning King Coal."

THE TELEGRAPH A NUISANCE.—To old-fashioned people—and most people are old-fashioned nowadays who have passed Thackeray's critical age of forty—the telegraph is an unmitigated nuisance. To begin with, it is enormously expensive; it has added to every firm's expenditure a constant drain of 2,000 dols. to 10,000 dols. a year, with no corresponding increase of profits or commissions. It wastes time to an incredible extent; the cost of every word has induced the manufacture of the most elaborate codes, in which the most impossible words convey deeply involved sentences. As all languages are used in the compilation of these codes, and no telegraph line can provide all its assistants with an unlimited knowledge of languages, mistakes are frequent, and the unfortunate recipient of a message wastes his time first in endeavouring to solve the riddle presented by a mistake of, say, two letters in an Italian pluperfect, and then in asking for a repetition of the unsolvable problem. It used to be one of the alleviations of exile that mails came in with the news with reasonable regularity, and one knew when one would hear from home, and when one would have to write. Whatever one's personal news, there was always a batch of newspapers to read, and for these, at least, one could greet with pleasure the sound of the mail guns. But the telegraph has spoilt all this; there is no longer sequence or continuity in the news we get. What in the old days would have been welcome as actual news in the *China Express* now comes in little scraps by Reuter or Indian papers, or from San Francisco journals, or from Australian exchanges, and sometimes from all four, until all our interest is destroyed by the scrappy and inconsequent form in which it reaches us. There was a time when we could attentively follow the progress of the training for the Oxford and Cambridge, or the betting for the Derby, or of some great trial; but now we get the result before we get the processes, and our intellect is as little satisfied as our stomach would be if we were given a teaspoonful of Liebeg instead of a well-served dinner. It was Artemus Ward who said that it would be money in his pocket if Columbus had never discovered America. Certainly life would be far better worth living if scientists had avoided the discovery of the electric telegraph. —*Celestial Empire, Shanghai.*

MAGNETIC STATION AT ST. MAUR OBSERVATORY.—This station was built last summer by Mr. Mascart, the director of the Paris Meteorological Station, and consists of a pavilion 23ft. long by 16½ft. wide, the short side being in the geographical meridian; this contains two vaulted caves, each ventilated on three sides by air-holes, which in the eastern cave are darkened, without, however, excluding the necessary ventilation. The instruments used in each cave for determining the magnetic direction and intensity are three, viz., the declinometer, the bifilar, and the magnetic balance, all mounted on masonry pillars about 6½ft. apart, those in the western cave being read directly by telescopes, while the indications of those in the eastern cave are automatically recorded by photography. To obtain a continuous record of the latter, Mr. Mascart has invented a magnetometer, which, while in no respect less accurate than the Kew one, offers the following advantages:—(1) Is considerably less costly; (2) requires a smaller magnetic cave; (3) em-

Digitized by Google

ploys only one lighthouse for the three instruments; (4) registers all the elements on the same sheet of paper. It consists of a case divided in two throughout by a wooden partition; the back contains the clockworks, while the front forms a dark chamber which contains the photographic slide moving in a grooved frame, which, by means of a rack and toothed wheel, driven by the clock, descends behind a window in the case once in every twenty-four hours. The clock pendulum oscillates in a plane parallel to the magnetic meridian. The light is supplied by a small gazogene lamp, which, well regulated, will burn steadily for thirty-six hours; by charging it at a fixed hour daily, a constant illumination is secured. The focus of the lamp is centred in a lantern fixed to the clock case, and fitted on each of its three free sides with a metal frame carrying a field lens and a vertical slit, which can be narrowed at will. One of these slits sends a ray to the declinometer, a second sends to the bifilar, and a third to the balance; and these are so arranged that the luminous images, after reflection on the fixed and movable mirrors of each instrument, are returned clearly upon the sensitised paper, one-third of the breadth of this paper being reserved for the indications of each instrument. Six traces are thus obtained upon the paper, three being the fiducial lines of each of the elements, and three the curves of their variations. The deviation of a curve to the right of the fiducial line for each element is proportional to the angle between the mirrors. The hour is also recorded upon the paper, the clock movement being arranged so that the grooved frame falls exactly 1 centimetre (0·4in.) an hour, the total curve-length being thus 24 centimetres (9½in.). The paper is pressed in the slide between two sheets of glass, one of which (the one on which the sensitised side rests) is transparent, and bears twenty-five horizontal studs, each 0·4in. apart; these studs appear in turn before the window in front of the photographic slide, and, by intercepting the light, cause breaks in the lines formed on the paper. The exact time at which each sheet is inserted is written upon it afterwards, as also the date; but all other inscriptions are made photographically. The slide is remounted, and the lamps renewed daily at mid-day.

Thunderstorms.—London and its neighbourhood were visited by severe thunderstorms on Saturday and Sunday last. When the storm on Saturday was at its height, about 4:15, a flash of lightning passed through the house No. 47, Walden-street, Mile-end Old Town. It entered the window of the first floor back room, where three children, viz., Mary FitzHenry, aged nine; Joseph, aged seven; and Kate, aged five years, were sitting at play. Joseph was thrown to the floor and rendered insensible, whilst the clothing of the eldest girl was set on fire, causing her to be severely burnt about the arms, legs, and body. The hair and clothing of the third child were also burnt, but she sustained no serious injury. The lightning then passed through the bed, setting that on fire, and through the floor into the room below, where it scattered the things about in an extraordinary manner. Shortly after the above occurrences the house No. 45, in the same street, was struck by the electric fluid, and the chimney-stack and roof injured.—The storms were severely felt in West Middlesex, where the lightning was intensely vivid and the flashes unusually frequent, but no fatalities have as yet been reported.—On Saturday, during the heavy thunderstorm, a man named Edwards, in the employ of Mr. Reynolds, landlord of the Golden Lion Hotel, at Romford, was blinded. The poor fellow was engaged in the yard of the Golden Lion with a pitchfork while the storm was at its height at about one o'clock, when a flash of lightning caught the steel end of the fork, the result being that the electric fluid was transmitted to Edwards's face. Edwards, who is a married man with four or five children, was taken to the surgery of Dr. Wright, and this gentleman, after examining him, found that the poor fellow's sight had been taken away.—During the thunderstorm on Saturday afternoon the electric current entered the Post Office at Wallingford, and so injured the telegraphic apparatus that no messages can be received or despatched until the instrument is repaired.—At Llanarth, near Raglan, in Monmouthshire, a man was killed while driving a mowing machine.—The astronomical observatory at Mitchel Troy Rectory was much damaged.—At Coleford two hay ricks were set on fire, and numerous trees have been shattered in the district, communication being much interrupted. —At eleven o'clock on Saturday morning a thunderstorm of unusual severity was experienced at Kingston-on-Thames. While the storm was at its height the lightning struck the flagstaff of Kingston Church, splitting it into pieces. Some of the splinters of wood were carried a considerable distance. One of the bolts securing the staff was carried away.—A heavy thunderstorm passed over Brighton on Sunday afternoon, and St. Matthew's Church was struck by lightning, considerable damage being done. The church, which has just been built in the east part of the town at a cost of £10,000, was only opened on Friday. The lightning struck the cross on the east side over the chancel, taking it completely off, and carrying with it a portion of the coping. The pole was splintered into fragments and fell into the yard below, the contractor's watchman having a narrow escape. The Sunday School children were in an iron building on the north side of the church at the time, and when the crash came rushed for the door, but through the presence of mind of the superintendent a panic was fortunately prevented.

Defence against Lightning.—Colonel Parnell, of the Royal Engineers, published recently in the *Newcastle Daily Chronicle* the following hints:—*Out of Doors:* (1). Persons obliged to work out of doors during the summer and autumn should carry *as little metal of any kind* about them as possible. [A rule of the most intense importance. Remember that nails in boots, buttons of trousers, money in pockets, metal on tobacco pipes, all are most attractive, besides such more palpable articles as rings, watches, studs, &c.] (2). If caught in a thunderstorm, endeavour to get inside the nearest *brick* or *stone* building before the thundercloud arrives over where you are. (3). If this be impossible on account of the absence of such buildings from your vicinity, and if you are already quite in the open and away from trees, or other shelter, *on no account move;* but let yourself get drenched, and if you can, lie down on your face till the thundercloud be past. [The object is to diminish your height above the surface of the ground as much as possible.] (4). *Avoid shelter like poison.* If you can get right inside a brick or stone house, do so; but do not stand just inside the door; and by no means go into *outhouses*, such as barns, stables, sheds, &c. But especially avoid mere temporary shelter, such as that given by trees, walls, cliffs, quarries, hedges, banks, hayricks, or other outdoor objects. (5). Wooden buildings of all kinds, and especially *wooden sheds*, are dangerous; but a low building wholly of metal (say a temporary church of corrugated iron) is not generally a source of danger. (6). If you have time to choose your position in the open, when the thunderstorm approaches, choose *low* ground rather than high, *dry* ground rather than wet, *rocky*, *stony*, or *paved* ground rather than grass, earth, or ordinary macadamised roads, and *leeward* sites rather than windward ones. [The choice of ground is of very great importance. It is almost certain that every lightning stroke *springs upwards*

Digitized by Google

from the earth and downward from the thundercloud simultaneously; and the chances of a thunderbolt occurring *at all* at a place are greatly influenced by the nature of the surface of the ground. (7). If labourers in a field have to leave their work, they should on no account take with them their hoes, scythes, hayforks, or other metal implements. *Indoors*: (1). Keep well away from the kitchen fireplace. If you can, go into some room or passage where there is no fireplace. [Chimneys are great sources of danger.] (2). Keep away from all walls, but particularly from the *outer* ones. (3). Especially avoid the neighbourhood of any *metals* on or near the walls, such, *e.g.*, as gas pipes, water pipes, bell wires, window bars and fastenings, sash weights, ventilators, door fastenings, cisterns, sinks, looking-glasses (on account of the mercury), pianos, gilt ornaments and picture frames, tie rods, cranes, rain water pipes, balconies. (4). Close all windows and doors. (5.) Keep your kitchen chimney clean. [Soot is very attractive.] (6). So far as lies in your power do not have any *metal* on the outside of your house especially in elevated places such as chimney pots and eaves gutters. [Elevated metal is usually the cause of buildings being struck.] (7). A piece of paving close round the walls tends to prevent a building being struck. (8). Keeping the ground around them dry and well drained has a similar tendency. (9.) Fixing a few sharp-pointed spikes somewhere on the ironwork of the kitchen grate, and at the same time connecting the bottom of this latter to the ground by means of a bit of old iron passing through the hearthstone and about six inches into the soil, tends to *tap* the ground of its dangerous electricity, and hence to avert lightning strokes. [These strokes are merely *explosions* of pent-up electricity.] In conclusion, it may perhaps interest your readers to know that the ravages of thunderbolts occur in all countries, chiefly among the *poor rural classes*. It appears from official records that the number of persons killed by lightning in the Russian Empire (exclusive of Poland and Finland) during the five years from 1870 to 1874 was 2,270, of whom 2,161 were dwellers in the country; also that, during this period 4,192 fires were occasioned by lightning in the same area, of which 4,099 occurred in the country. My own impression on the subject of the defence of the United Kingdom generally from these dreadful thunderbolts is that Government should for a few years scientifically examine and minutely record every fatal or destructive lightning stroke that may happen in Great Britain and Ireland, and should make some attempt to interpret the laws, meteorological, geographical, and physical, which Nature follows in these wonderful manifestations.

THE EASTERN TELEGRAPH COMPANY.—The Four per Cent. Debenture Stock now being issued by the Eastern Telegraph Company at £95 per £100 stock offers exceptional advantages to investors, not only when compared with the existing debentures of telegraph companies, which are of a temporary character, and liable to be paid off in a more or less limited period, but in comparison with the similar stocks of railway companies. The Eastern Telegraph Company possesses main trunk lines of cable which join India to England, and touch only at places owned or controlled by the English Government. The permanence of this great and important means of communication with the East is assured by the existence of several independent lines of cables belonging to the company. These are kept in so high a state of efficiency that interruption of communication is hardly more likely to occur on these lines than on the railway between London and Liverpool. But, even should a temporary interruption happen, communication can be infallibly repaired in a very short period, and the company, by its arrangements with other telegraph administrations, would lose hardly any revenue. In addition to the trunk cables to India the company owns a network of submarine telegraph lines joining all important points on the Mediterranean and Black Seas, and rendering communication between England and the various countries and places served by the company more rapid and secure than could possibly be effected by land wires operating over such great distances. The income of the company has always been large, and has latterly made steady progress, the following being the net income of the past five years, after paying all expenses, including the cost of repairs:—

Net income year ending	March 31,	1879	...... £269,037
Ditto	ditto	1880	 346,965
Ditto	ditto	1881	 367,522
Ditto	ditto	1882	 368,881
Ditto	ditto	1883	 400,776

During this period the capital of the company has only been increased by £345,000, the additions to capital in the two years since March, 1881, having been only £7,000. On the other hand, in the same period of five years, the reserve funds have been increased from £159,224 to £569,828, or by considerably more than the total additional issues of capital, while a large amount has in the period been paid for out of revenue on account of the purchase of a maintenance ship and the expenses of the steamers laying new cables. The present total annual charge in respect of debenture interest absorbs only about 11 per cent. of the net available income of the company, while it is common to see similar charges in English railway companies of first-class standing absorbing 20 per cent. and more of the net revenue. The mortgage debenture stock now being issued will be a first charge on the undertaking and revenue of the company, and the company's power of issue is strictly limited to one-third of its paid-up share capital, so that, were the whole of the borrowing powers immediately exercised, and were no increase or income to result from the additional capital outlay (which is, to say the least, improbable) the charge for the service of the Debenture Stock would absorb only £60,000 out of a net revenue of over £400,000, being at the rate of 15 per cent. of the net income, showing an unusually large margin to cover any possible loss of traffic, additional expenses, or other unforeseen contingency. The magnitude of the reserve fund provides a security which, it is believed, is unprecedented in any other class of business enterprise, the present amount being nearly £570,000 against a total present bonded debt of only £882,000. The price at which the Debenture Stock is now issued, viz., £95 per cent., gives a return to the investor of slightly more than 4 1-5 per cent.; the existing Preference Shares of the company, at present quotations, give a purchaser barely $4\frac{1}{2}$ per cent., and this latter security ranks necessarily after the whole of the authorised indebtedness of the company. The following table compares the return to an investor in the Eastern Telegraph Company's Debenture Stock with that obtainable by a purchase of railway debenture stocks according to the prices current on June 30th last:—

STOCK.	Price June 30.	Yield per ct.
Ln. and Nth. Wst. Rly. Four per Ct. Deb. St.	117 ...	3 7 6
Gt. West. Rly. Four per Cent. Deben. Stock	115 ...	3 7 6

POTENTIAL, CURRENT, AND RESISTANCE.

BY JOHN T. SPRAGUE.

In Vols. II. and III. of *The Electrician* there was a prolonged discussion on the subject of Potential, in which several eminent electricians took part, and which, if it did not clear up the subject, made it very clear that there existed much difference of opinion about it. In papers by myself at a later period on the transmission of large currents, the constants of the electric current, and current force and energy, I endeavoured to work out some ideas of my own as to the nature of electromotive force, and the analogy between electric currents and those of water, but did not carry this out completely. Having had recent occasion to examine the subject again, with the result of further developing some points which appear to be of interest, I propose now to present them fully worked out, though in so doing I must of necessity again go over the matters contained in former papers. As force is the origin of action, conduction its channel, and current the result, that order of consideration might appear reasonable, but these divisions cannot be wholly maintained, and I do not propose to attempt it, but shall take the various subjects as they come convenient.

1. Current is most easily conceived because it deals with actual tangible facts in nature, while the others are matters of calculation. Current in electricity, as with water, means the rate of passage of unit quantity across any section of the conductor; its most definite evidence and measure is the chemical action produced by the passage of electricity through liquids. Unfortunately, the accepted unit of electric quantity, the coulomb, does not accord definitely with the natural unit

$$\frac{\text{Atomic weight}}{\text{Valency}} = \text{electric equivalent},$$

which would make one of hydrogen represent the unit of electric quantity, and, with the element of time, the unit of current; but though only a fractional value represents the relation, and it is not even settled whether the real value of the coulomb and ampere is ·00001022 or ·000010415 of a gramme, still this is the true physical representation of electric quantity, which corresponds to "mass" in mechanical calculations.

2. In the older works on electricity "quantity" currents and "intensity" currents were spoken of, and even now we occasionally meet with such an unmeaning phrase as the "tension" of a current. All such ideas, which give the impression of some difference of nature in currents, are misleading. Current, as such, has only one quality, its rate; a given current, that is one which will produce a certain deflection in a particular galvanometer, or will deposit a certain weight of metal from a solution, is exactly the same in its nature and properties whether it comes from a large or small cell, from a single cell, or from a thousand cells in series. But the same current may have different effects according to its *density*, that is according to its ratio to the sectional area of the conductor, or its quantity per unit of area. This influences the temperature generated in wires, and is of supreme importance in electrolysis, so that it is unfortunate that some writers have taken to using the already misapplied term "intensity of current" for this ratio.

3. Ohm's Laws.—These laws or formulæ are universally employed by electricians, but are not confined to electricity, as they express the common fundamental mechanical laws. The relations established by Ohm's laws between electromotive force, resistance, and the current and its work, are simply the well-known laws of mechanics or the relations between force, such as gravity, weight, and velocity; and the laws themselves are merely mathematical expressions. Invaluable in dealing with the modes of operation, they only delude us if we regard them as facts, and do not clearly trace out the reasons why they are valuable. Mr. Oliver Heaviside has made some remarks on this subject (pages 149 and 150), in which this matter seems to be curiously undervalued, when, after referring to the confusion in some minds as to electric resistance, he remarks that "R is just called so," and again, "if ideas are correct it is of secondary importance what language is used to express them." But that is just the point; a writer's idea may be correct, but when he has to use words which have already an entirely different meaning, it is by no means sure that his readers' ideas will be correct. It is in fact only quite lately, and in no degree consequent upon the teachings of the professional teachers of electricity and their formulæ, that people are beginning to understand that R, the electric *resistance*, is not resistance at all as commonly understood. When he suggests that the fact that this so-called resistance presents no more obstacle to a large current than to a small one (p. 199) is a powerful argument in favour of providential design, one is apt not only to smile at his suggestions of a soporific, but to doubt whether he has himself fully realised that the fact itself results merely from an arithmetical artifice explained in my earlier papers referred to, and which I shall recur to in due course.

Multitudes of students are misled by this misuse of the the word resistance, and eminent electricians and engineers have been equally deluded. Mr. Siemens said in a public lecture:—"My critics have, however, fallen into the error of overlooking the fact that half a unit resistance is the same for a circuit capable of working one lamp as it is for working 100 or 1,000 lamps. *Electricity is not conducted upon the conditions appertaining to a pipe conveying a ponderable fluid*, the resistance of which increases with the square of the velocity of flow." Sir W. Armstrong, in his address to the mechanical section of the British Association in 1881 says:—"In the case of a fluid current through a pipe the resistance to the flow increases as the square of the velocity, while in the case of an electric current the resistance through a given conductor is a constant proportion of the energy transmitted. So far, therefore, as resistance is concerned, electricity has a great advantage over water for the transmission of power." So we may see that by converting mathematical formulæ, which are nothing but mental tools (apparatus for mechanical thinking in some sense), into actual facts and theories, electricians have actually been led into great errors as to the nature of the electric constants.

In these quotations we have two distinct statements—1st, that in electricity a resistance is the same to all currents transmitted; 2nd, the sentence italicised, that currents of electricity and currents of water depend on different laws. Most electricians then, and many of them now, would endorse those statements. I dealt with them at the time in the pages of *The Electrician* and the *English Mechanic*, and will now show clearly what is really the thing that is alike for large and small currents, and also that *water in pipes and electricity in wires are conducted upon identical conditions.*

4. The fundamental expression of *Ohm's laws* is $\frac{E}{R} = C$, which means force (or more correctly "potential") divided by resistance defines the current, or rate of flow.

It follows that any two of the three elements, E, R, and C, being known, we can calculate the third thus, using the units of the B.A. system: the volt for E.M.F., the ohm for resistance R, and the ampere for current C.

Current.—$E \div R = C$. Force and resistance being known.

Electromotive Force.—$C \times R = E$. Current and resistance being known.

Resistance.—$E \div C = R$.

Energy $= C^2$, the square of current, in unit, or unaltered conductor, or $C^2 \times R$ as a general law.

5. The usual expression of the meaning of the formula is, *current* is *as the force* and *inversely as the resistance.* In order to fix the mind upon the ideas I wish to develop, I give this modified definition: *Current* is *as the E.M.F.* (which is *potential*), and *as the conducting capacity.* That which in the usual expression *is called resistance*, is simply the *reciprocal of the conducting capacity.* It has nothing to do with anything commonly known as resistance.

6. According to these relations, C varies as E, but energy, as work or heat, *which are the true resistance*, varies as E^2,

Digitized by Google

that is as the square of either C the current, or E the E.M.F., in unit or any unaltered conductor, and it also varies as the so-called resistance; that is to say, it is inversely as the conducting capacity of circuits. This is precisely the ordinary law of mechanics, say in friction, where work absorbed is as the square of velocity, and directly as some other element, such as weight.

7. The very first point as to which a clear understanding is necessary is whether these symbols E, R, and C have any realities behind them. Do they represent facts, and if so, what facts? Or are they merely mathematical expressions, simple tools of thought? If the latter, we must carefully avoid the error of mistaking them for facts, lest, like the monster Frankenstein, they prove too much for their creators. It will be more convenient to examine this while studying Ohm's formula as a whole, than to treat each head singly.

8. *Electromotive Force.*—Is the E.M.F. which we symbolise by E *a force?* Let us see what idea we can form of it. A force tending to set electricity in motion; or, to use a better phrase, to set up that motion which we call electricity. Here it will be seen we have two considerations presented to us: an effect, the motion produced; a cause, the force producing the motion. Of these the first, the motion, is of necessity an actual fact, though we may hold different ideas as to what is the thing. But does the *cause*—the *force*—exist, that is to say, the special force? There are actual forces having real existence, such as the various attractions, of which we may take gravitation as the type; these are, so to speak, self-existent—we know not their causes. But there are other agencies which we call forces, yet which have no actual existence. They are really transformations of energy, and are forces only in the mathematical sense.

9. *Development of E.M.F.*—When we dissolve zinc in a battery this force makes its appearance. It is said by some to be due to the contact of the two dissimilar metals. But one thing is certain—this force can do no work unless it is maintained by an equivalent supply of energy, and, as a matter of fact easily proved, the degree of electromotive force produced is measurable in terms of the energy transformed in its generation, which is measurable by the heat set free in the chemical combination.

But if we expose the junctions of two different metals to heat, we find electromotive force set up in degrees depending (1) upon some inherent property of the metals, and (2) upon the difference of temperature produced, which means, in fact, the quantity of energy which can be thrown into the circuit.

Similar results are found when we examine the E.M.F. set up by dynamo machines. It bears a definite relation to the energy expended. We find also that though electromotive force is constantly acting upon the circuit, it has no accelerating action. We therefore conclude that it has no actual existence, but is due to conversion of energy, and that it must in some way be equivalent to the energy which it expresses.

The effect of the ideas about to be presented is to show that E.M.F. is no occult effect of *contact*, or of cutting lines of force, &c.; that these are but "conditions;" that E.M.F. (or potential) is always an expression for, a measure of the effort of energy (potential or kinetic) to take the kinetic form under any particular conditions.

10. *Any agency may be called a force* which is capable of setting up motion, or altering the conditions of motion in a mass of matter. Thus, if we take a ball of lead and let it fall, motion is imparted to it by gravitation. We may push the same ball of lead along a table, or by muscular energy hurl it to a distance. We may strike it, as a cricket ball is put in motion, by a percussive blow; or we may, by aid of a gun, set it in motion by means of compressed air, or by the explosion of gunpowder. In all these cases motion is produced, and we may call the agency in each case a "force."

11. *Mechanico-Motive Force.*—We may embody all these in one expression, and say they are due to a "mechanico-motive force," the intensity of which can be measured by its capacity to produce momentum. Of course the object of this term is to obtain an exact mechanical counterpart to the electric expression, but this term, or something like it, has actually been employed in mechanics. We have then to see whether this mechanical analogue is a force, or what is its true meaning.

12. *Static and Dynamic Force.*—There are two ways of treating and measuring a "force." (1) By the *pressure* it produces. This is a static action, and it measures a force as a *degree*, not as a quantity. A force so regarded is an abstract property or power; it has no relation to energy, because it does no work, though it has a relation to *potential energy*, as will be seen later. (2) By the motion it produces in matter, and this, again, has two aspects. 1. *Velocity*, which may be general or abstract, as in the case of the force of gravitation when expressed by the ordinary symbol g, meaning its capacity of generating a velocity of 32·2ft. per second. 2. *Momentum*, in which the force becomes concrete and *quantitative* by the introduction of unit mass of matter, and unit time. But this is no longer true *force*, it is an expression of *energy*—of the work a force can do under unit conditions. The *dyne* is such a force, or, more truly, a mathematical expression for a unit quantity of force, and it is the same value, in reality, as the *erg*, the unit of energy. They are simply expressions for the two aspects, *cause* and *effect*, force and work, which of necessity are equal. This will, of course, be objected to by the mathematical minded; but this is a case where truly, "if the ideas are correct, it is of secondary importance what language is used to express them." The idea is an inevitable consequence of the conservation of energy. *Force expended and work done must be equal*, and the purpose of my statement as to their units, the dyne and erg, is just to impress that fact. The usual plan of regarding them as belonging to distinct orders is directed to another purpose —their practical application.

13. *Gravitation* as a natural force therefore produces (1) a static pressure (2) a velocity (say 32 feet per second) (3) a momentum in a mass (say 16 feet lbs. per second). It also produces *acceleration*, that is to say, acting continuously its effect is accumulative. This property would be important in a treatise on mechanics, but does not necessarily enter into the electric treatment of force; its effects are included in the actual velocity and momentum generated. But it may be well to point out that the ordinary conception of gravitation, as due to the attraction of the earth for movable bodies, is misleading, because it leaves out of sight the part played by the second body itself. The effect of this is that while we can express a spring or steam force as a pressure of so many pounds per square inch, we cannot so express gravitation *per se*. We shall deal with such a pressure presently as "head of water," but this is a compound expression. Besides the attraction of the earth, it includes that of the water itself, that is, its own weight (or more properly mass). Of course it is perfectly known that this attraction is really that of the two masses, earth and body; it is only the common way of thinking that I refer to, which reacts even upon science. In our utter ignorance of the real cause of gravitation, we fix our ideas upon the mere masses of matter, and satisfy ourselves with the statement that it is $\frac{M \times M^1}{D^2}$, and in that formula we bury away the agency itself, the most perfect representation we can find in nature of an omnipresent consciousness.

14. We wind up a spring, and we know we have stored our work in it. We wind up a weight, and we know we have stored our work in it. We speak of "potential energy" in both cases, but in how different a matter do we think of the two agencies of storage. One seems real and the other mythical; the one we call energy of *stress*, molecular strain; the other we call energy of *position*. But let us conceive a powerful spiral spring attached to a rope passing over a pulley, and thence to a winch by which the spring can be strained, or wound up. We have here a tangible agent to deal with. We see the strained spring, and we know that the spring, by virtue of that strain, will return us our energy by doing work equivalent to that employed in generating the *molecular stress*. But we replace the spring by a mere weight which we wind up, and then we talk of energy of position. It should be clearly realised that

Digitized by Google

the two conditions are identical; in winding up the weight we have in some way, wholly unknown to us, put *a stress upon the earth* and stored energy just as certainly as in the spring. We do not know how, but in some way the force of gravitation is as surely an expression of energy stored up in matter as is the attraction exerted between two charged electric surfaces across the strained dielectric, which is expressed by the same formula, $\frac{Q \times Q^1}{d^2}$, and by the equivalent magnetic law, all these so-called quantities being, in fact, simply measures of the stresses or attractions exerted by forces.

HONOUR TO WHOM HONOUR IS DUE!

EDWARD DAVY AND THE ELECTRIC TELEGRAPH, 1836 TO 1839.

BY J. J. FAHIE, MEMB. SOC. TEL.-ENGS. AND ELECS.

(CONCLUDED FROM PAGE 212).

Mr. Davy's correspondence, which was broken off in our last impression, proceeds as follows :—

June 16, 1838.

My Dear Father: I have only time to say that I received from Messrs. Gibbs £130, and Mr. Carpmael informs me that the patent will be sealed early in next week. I must write you again to explain what I purpose doing as soon as that is accomplished, viz, to send circulars immediately to all the Boards of Directors of Railway Companies, and to give one, or more, public lectures on the subject, inviting as many influential people as possible to attend. It must now be pushed forward with all our might and main, and I hope it will not be long before it does some good.

You will soon hear from me again, and believe me,

My dear Father,

Your ever affectionate Son,

E. DAVY.

June 23, 1838.

My Dear Father: I think that I ought to give you notice from time to time of my moves with the telegraph, in order that, in case of any sudden accident to me, and the concern being in a promising state, my successors might know better where to take it up, and what I had been doing.

The patent has not yet passed the seal. I expect that it will about Wednesday, or Thursday next.

I have been endeavouring to make connections with some business men, to assist me in making negotiations with the railway companies, or in getting up a general telegraph company.* The principle on which I endeavour to engage their services is that of percentage on whatever money I may obtain for licenses under my patent, through *their particular influence, or interference.* The amount I have fixed upon is 10 per cent., which will perhaps be liable to deviations in some cases. The present difficulty is in getting the thing *started.* When known practically and appreciated, it may be that the companies will come to me, instead of my having to seek after them.

The best business man I have at present retained is Mr. P—— * * * * I requested him to apply first to the Birmingham Railway Company, and the subject has been brought before the directors. The only answer obtained is that, if ever the directors should deem it necessary to adopt any electrical telegraph, they will make the most minute and careful examination into the comparative merits and advantages of each plan before deciding on either. I saw Mr. Creed, secretary to, and original getter-up of, the Birmingham Railway Company, who told me only that he would be happy to receive any memorial from me on the subject of my invention in order to lay it before the directors. Mr. P. is to introduce me to their domestic engineer in about a week.

* * * * * *

Mr. P. is next about to apply to the Southampton Railway, and I am now preparing letters* for him to make use of, setting forth that, when once laid down, the Admiralty will, no doubt, be glad to make advantageous contracts with them for the use of it for Portsmouth, which is at no great distance.

We must, of course, rake our brains to find out all the inducements we can to tempt people to these speculations.

That will be the next move. Then there will be the grand junction from Birmingham to Liverpool and Manchester.

The next business man I hope to retain, and have partly, is Captain B——. He is intimate with the engineer of the Birmingham and Gloucester Railway, and has influence with the Midland Counties Railway, either of which would be a good step.

Another is Mr. B——, of whom you have heard before.

* * * * *

I have an appointment to meet a capitalist, name as yet unknown, at three o'clock on Monday about money for taking out the foreign patents, all which may, or may not, come to nothing. Another appointment with a broker, named L——, to aid in getting up a company, at four o'clock the same day. There are many of these appointments for the one that leads to any result. Therefore, do not be on the look-out for such results, I will be sure to tell you if anything good comes. It is no use to be either sanguine, or easily put out of one's opinions.

Believe me, my dear Father,

Your ever affectionate son,

E. DAVY.

P.S.—My impression at this moment is that it will be better, if possible, to get up a general company, and sell the patent out and out, particularly as the Birmingham directors scarcely appear to comprehend the advantages of the system further than for mere railway uses. It will, I know, be a very difficult matter to get the proper people in the mind for entering into such a scheme. Mr. Hesseldine appears to listen to the proposition, but has some objections of which I cannot clearly see the drift, unless it be this—that the Government could scarcely allow such a powerful instrument to be in the hands of individuals, or a private company, and would either prohibit it, or else take it under their own management; and, therefore, that the best possible parliamentary, or government, influence ought to be made in order to secure the probability that such future arrangements with the Government may be advantageous to us.—I know very well that the French Government would not permit it except in their own hands; but though I think our Government ought, *and, perhaps, will eventually, take it upon themselves as a branch of the Post Office system,* yet I can scarcely imagine that there would be such absurd illiberality as to prohibit, or appropriate it, without compensation.

There is, however, prudence in what he suggests as to making friends in high places, if it can only be done.

Are there any of the Directors of the Bristol and Exeter Railway with whom interest could be made? They are, I believe, in great part Exeter people.

4 July, 1838.

My Dear Father: It was not until this morning that my patent actually passed the Great Seal. It is now secure for England and Wales, and you will see it in the list in the next *Gazette.*

The enclosed was written some time back. It may be well to preserve whatever details I send you with regard to the telegraph.

My object now is to get a company formed to take my patent off my hands, and, either pay me a large sum down for it out and out, or else a smaller sum down, and an agreement for a further remuneration hereafter, and proportioned to the success of the scheme, such as a percentage on dividends, etc.

* * * * * *

There is plenty of money in the market, and plenty of people ready to vest it in such schemes, if they can only be satisfied that they will pay more than 5 per cent. interest. All I have

* A few letters to and from business men and Railway Boards on this subject are preserved amongst the Davy MSS.

* Original drafts of these preserved.

to do is to make people believe this, and the money will come without any pressing on my part. But this *is* the difficulty, and one which I have now to make every possible exertion to overcome. The practicability of the plans will, I believe, not be much longer doubted. I have several persons at work to get some influential names sufficient to head a prospectus* as Directors, &c., and find current expenses of printing, advertising, journeys, models, &c.

* * * * *

Mr. P. says that "before forming a company, we must first secure the consent of some railway company to the laying down of the wires upon their line on certain terms. If one railroad will do this, we may afterwards reason that others will agree to the same; otherwise people will say, 'How are you going to enforce permission from the railways, or turnpike trusts, without an Act of Parliament'?" Now, I don't see that the want of previous agreement with a railway should at all deter us from endeavouring to form a company, but it is clear enough that such an agreement, previously obtained, would be a step gained, and an argument in our favour. With this view an appointment is now pending with the domestic, or resident, engineer of the Birmingham Railway.

* * * * *

I have had notice of another application for a patent by a person named *Morse*. Messrs. Cooke and Wheatstone have entered an opposition to this application, and I shall have to do the same, so that one, or other, of us may be able to stop it. We are now both equally interested in keeping a third rival out of the field, and it may save much after trouble and competition. * * * * *

Your ever affectionate Son,
E. Davy.

In a letter to the same address, dated July 21, 1838, the following passage occurs:—"I find the people who undertake to make appointments about the telegraph very dilatory in so doing, which prevents my making progress as fast as I could wish. I trust the prospectus will be a help.

"It is not every one who is willing to be a director that will suit, as I wish to confine it to the highest respectability, and avoid all poison. Mr. E— has evidently his enemies, but if I can find that he has also his friends, he will be a valuable acquisition, having much money and connections, and I believe he would liberally support me, or lend his voice to pay me a large sum."

Two days later he wrote:—"I had a further conversation with Mr. P— on Saturday. He expects an appointment with the engineer in question [? Mr. Fox] on Tuesday, and entertains a hope that we may also secure Mr. —, the chairman of the Southampton Railway Company, than whom, for one, we need not have a better. Mr. P— having considered the prospectus, and suggested some slight alterations, said that, now the thing was distinctly laid out, his views had quite altered, and he should have a difficulty in seeing how the thing should do otherwise than 'pay' to the shareholders. He would be the managing director, or whipper-in, as he is in the A— Mining Company. As I have but slender acquaintance among the great commercial people, I am obliged to apply to, and make use of, persons of this kind, and I believe he is well known and knows many, and that his persuasion may have some effect, where I should not be listened to. The difficulty is to get him to stir himself sufficiently. I do not anticipate much good from either Captain B—, or Mr. B—, but perhaps they may be of some aid."

30th July, 1838.

My Dear Father: * * * * * I had an interview on Wednesday last with Mr. Fox, Resident Engineer of the Birmingham Railway, the whole particulars of which I can scarcely enter upon at this moment, except that it was quite satisfactory and friendly, as far as it went. The main purport of it was that if we had a Company who would go to the expense of laying down the wires, &c., the railway directors would willingly grant the use of their line and afford every facility and protection, on condition only of a license under the patent as far as relating to railway purposes only.

This has been one of the problems, "How is the Telegraph Company, without an Act of Parliament, to lay down the wires?" He says there is no doubt that few of the railway companies will object to these terms. Mr. P— has promised to-morrow to see the Southampton Railway people, and I shall have another interview with Mr. Fox, for further explanations, so that I trust we shall soon be enabled to come before the public; but it is a tedious business. 31st July.—Since writing the above I have received M. A.'s letter and enclosure, to which I shall give the earliest attention. You may presume, if you do not hear from me for some little time together, that there is nothing particular going forward. I understand the directors of the Great Western Railway are under discussion to ascertain the nature of my patent, but I shall take no notice at present.—With kindest love, believe me,

My dear Father,
Your ever affectionate Son,
E. Davy.

In a postscript to a letter dated Aug. 1, 1838, he writes:—

"I spent yesterday evening with Mr. Fox explaining my inventions to him. He expressed the most favourable opinions of them, and, if he does not alter his mind, we may consider the Birmingham line as secured, or nearly so. He is the sharpest and quickest man I have yet had to talk to, comprehending everything before it was half explained, and suggesting improvements, or remedies for difficulties, &c. We are in other quarters making slow but, I trust, effective progress, and the chances against eventual success appear daily diminishing."

17th August, 1838.

My Dear Father: Mr. P. has had interviews with Mr. Easthope and his son. Mr. E. seemed to take very enlarged views of the applications of the telegraph, and the revenues to be derived from it, and promised his strenuous influence for its immediate adoption on the Southampton and Portsmouth line, of which he is chairman of the directors. The conversation, as repeated to me, coincides with my own (perhaps sanguine) idea, to an extent which I have never had the satisfaction of meeting with before. Mr. P. came home quite red-hot upon the matter, sees it in a new light, and has this morning agreed to take out the principal foreign patents (to find the money and have half), on condition that I would also give him a further interest in the English patent already obtained. I have, consequently, agreed that he shall pay me £150, and have one fourth of the patent right. This I have done, not but that the patent may be worth far more than four times £150, but with ulterior objects, to secure his interest and exertion to help it on, for I could do little by myself. And it appears to me the remaining ¾ may be thereby increased in value more than they will have lost. I do not suppose that Mr. P. will go from this arrangement, which yet remains to be executed. He says, that, if sufficiently interested, he will devote nearly all his time to it.

I spent yesterday evening and took tea with Mr. Fox, resident engineer of the Birmingham Railway. I have his decided approbation of my plans, in preference to those of the other party, and, therefore, a powerful voice is secured on that line. We had much conversation on various details of the subject, but it takes time to work people into an acting humour. Until now Mr. P. has been lukewarm, or, at least, tardy, in his movements. The encouragement, which Mr. Easthope has given, has put a new life into the thing.

I believe I told you that Mr. Easthope is a Member of Parliament, proprietor of the *Morning Chronicle*, and a large shareholder in the Southampton, and in the Havre and Paris Railways. He is, perhaps, as good a patron as could be obtained for one. He said that the subject was not new to

* A draft of such a prospectus, headed "Voltaic Telegraph Company," is preserved in the Davy MSS. It is a powerfully-written and exhaustive document, and will well repay perusal. *Apropos* of the name, the following memorandum may be quoted:—"A satisfactory name is not yet decided on. It might be called the 'Oerstedian,' after Oersted, the Danish philosopher, who first discovered the magnetic powers of electricity; or the 'Instanterian;' but a better name may turn up." In another place Davy speaks of a system of *Electroloquism!*

Digitized by Google

him, and that it had been frequently under discussion in society where he had been.

You will perceive that if I have been in error as to the prospects of this invention, I have now some people of high standing to keep me in countenance in the "moonshine." Mr. Easthope speaks of its opening communications between London, or Liverpool, and the Mediterranean! With kindest love to all the circle, believe me, my dear father,

Your affectionate son,
E. DAVY.

About the end of August, or beginning of September, 1838, he wrote

My Dear Brother,—

I have just received a packet enclosing, among others, a letter from you. You will perceive by my communications to father, &c., that I am trying hard to dispose of my telegraph. I wish to get it clean off my hands, and, if possible, an employment in laying it down at an annual salary. I believe I may now almost calculate on the Birmingham Railway, the best line in the kingdom; there is little now to fear from the rivals, Cooke and Wheatstone, and there are no others. My object is to form a company of affluent people, who will purchase my patent right, and, if this succeeds, it will produce a large sum of money, as £10 or £20,000, just as easily as so many hundreds. The value of the invention has very greatly increased since what it was six months ago, and I would not now sell it to Cooke and Co. for any sum they would be likely to offer, and which I would gladly have accepted once. I have every assurance that I shall get together a set of wealthy directors, and that the shares will be taken up. We have, as you will perceive, some first-rate people already engaged, and much interested in it. Mr. Wright could, if he chose, advance £200,000. We are promised the Marquis of Douro and Lord Sandon for trustees, through the interest of Messrs. MacDougall, the solicitors in Parliament-street. There is no present reason to apprehend but that I shall get my price for it by persevering and securing influence step by step. But for all this, my presence here is indispensable. It would come to nothing if I left London at this juncture which would be madness. There is no one able, or willing, to push it forward for me, and, if allowed to sleep, the patent would not be worth a rush. I am now anxious to connect with some sharp, wary solicitor, not too young, whom I can engage to protect my own personal interests in driving the bargain with the directors, which will be very essential—one is so apt to be talked over by these keen monied men.

* * * * *

The enclosed piece of paper contains a statement of the progress made in organising our company. Only the names with asterisks are fully secured, but the others we have not much reason to doubt of.

When a meeting of the directors can be called together, I shall propose that as soon as the deposits are paid up they give me £10,000 in money and one or two thousand shares; in fact, the best bargain I can make. Something will come of it.

Your ever affectionate brother,
E. DAVY.

P.S. Exeter Hall cannot be said to pay at present. It is kept open rather to answer a purpose in getting up the company.

The above letter, as appears from another to his father of September 9, 1838, was written to his brother, Henry Davy, about the end of the previous month.

The piece of paper referred to contains the following:—

TRUSTEES.
Marquis of Douro, and Lord Sandon.

DIRECTORS.

*Sir F. Knowles, Bart., F.R.S.	Mr. Bagge (of Norfolk), M.P.
*John Wright, Esq., Banker.	Mr. Harrison (Chairman of the Southampton Railway
Em Tennant, Esq., M.P.	

ENGINEER.
Mr. Fox.

SUPERINTENDENT OF MACHINERY.
E. D.

SOLICITORS.
*Messrs. M'Dougall and Co.

Capital £500,000 in 10,000 shares, £50 each, deposit £5.

In a letter to his sister, dated September 22, 1838, he says:—

"I am obliged to remain in, or near, London on account of the telegraph, as there is a probability that the arrangements with the Southampton Railway will soon be completed. Nothing is certain as yet, but the Directors appear decided upon having one on their line. The Birmingham line also is in prospect.

"I have sent a circular to all the principal Railway Companies. The Grand Junction say they have no intention of adopting any telegraph at present, and the Birmingham and Derby seem to imply, in their answer, that they have it in contemplation, and will take it into consideration as soon as they are prepared to do so, &c. All that could be expected from the circular was to prevent them from engaging with the other party before they knew anything about me.

"The idea of forming a Company is suspended for the present, on account of the opinion of the Southampton Railway Directors, that all the railway companies would eventually take it upon themselves and find the capital. If so it is all that is wanted.

"I presume that if terms are made with the Southampton, which is the first company that is likely (being on the line of the Government Telegraph to Portsmouth, and having a probability of a contract with the Admiralty), they will require me to superintend the laying it down at a salary, independent of the remuneration for license under the patent."

On October 8, 1838, he writes to his father:—"I have done all I can to bring my patent before the Southampton Railway Company, and have received every assurance as to their intention of adopting it. I must now wait their final decision if they do so, as to the precise terms, and also as to the time when they will be ready to commence operations. What I have proposed to them is, that they shall be at all the expenses, pay me one-third of the net profits, and employ me, at a reasonable salary, to lay down the telegraph and keep it in repair.

"I will shortly make an attempt to urge forward the Birmingham Company, where, I believe, I have sufficiently secured the preference. As soon as one of these companies brings the telegraph into operation along the entire line, and it is found to answer, the others will quickly follow.

"The Polytechnic Institution, after giving much trouble, declined purchasing the Exeter Hall model, and I am now in treaty for it with a Mr. Coombes, an American, who proposes to take it home with him, and open an exhibition, with some other models, in his own country. I have closed the Exeter Hall room, and paid off Mr. Spicer, my assistant, and also Downy, the other man who used to attend there."

Again on November 17, 1838, he says:—"I have made some arrangements with Mr. Watson, rather on the principle of co-operation than of actual partnership, and have pretty well explained to him how I am situated. * * *

"You will perceive I am anxious to be doing something, independent of my expectations from the telegraph. I have put it into as good a position as possible, and have no doubt of its final success; and must now wait the answer from the Southampton Directors, who have verbally promised its adoption, as well as from other quarters. I shall not let the matter go to sleep, but as it is in a channel, and as my interference will not hasten it, there is little to be gained by thinking of it; so I must be doing other things.

"There is no relying on Mr. P. He agreed to purchase a fourth of the patent for £150, and was red-hot to conclude the bargain, but after a few days he told me that he could not at present provide the money? I cannot help these disappointments.

"Mr. Fox is steadily friendly to me as yet."

Digitized by Google

29th Nov., 1838.

My Dear Father: * * * * I have got rid of my room at Exeter Hall, which, now it is no longer required, is a saving of 14s. a week. Altogether it has somewhat more than paid its expenses, or thereabouts. It would doubtless have done better, but I was driven from personally attending to it by incessant annoyances. It has, however, answered more effectually by the notoriety which it has given to the telegraph. You will perceive by a number of the *Railway Times* which I shall enclose, a reason for the delay in the decisions of the Southampton Company, viz., the question whether they would obtain the branch line to Portsmouth. Mr. Easthope is a spirited man, by whom many other monied persons are guided, and he has influence with the present Government. I have as yet no reason to doubt that he will keep his word with me, that my telegraph shall be adopted immediately they are prepared to commence operations with it. The bringing this to bear may be a work of some little time, as such things usually are, but I am sure you will not regret the attention I have paid to it, nor even the manner in which it has diverted me from my other business; nor do I think you need feel doubtful as to its eventual success. The next month will be occupied with completing the specification (due Jan. 4), much of which will have to be remodelled by Mr. Carpmael's direction. Everything depends upon this being as perfect as it can be, and I wish I were more fit for the task, by having a mind more at ease than is at present possible.

* * * *

I have to-day been informed that the Brighton Railway Company are about to adopt an electrical telegraph, which is a quarter in which I scarcely expected it. I must look after them to ascertain if it is correct, for Mr. Cooke is making all his interest. I think the London and Dover will be a better line, but will not be complete for a long while. I am obliged to employ a good deal of Nickolls' time on the working model, which will be the principal thing in the specification, in order that it may be ready to show at work. The month after the specification is enrolled it will appear, at length, in the *Repertory of Arts*, a number of which I shall purchase and forward to you. With kindest loves to mother, brothers, and sisters, believe me, your ever affectionate son,

E. Davy.

December 12, 1838.

My Dear Mother: * * * * * My specification must be enrolled by the 4th January, and afterwards will be published, gratuitously, by the patent agents, in the *Repertory of Inventions*. This also I shall have to look to, procure a few copies, and send them to the parties most likely to serve us. After this, for aught I know at present, there is little more I can do to forward the matter, and it must wait the good time of the railway directors to take it up, which there is no reason to doubt nearly all of them will do eventually.

I believe I have effectually barred any hasty adoption of Cooke and Wheatstone's telegraph, which has made no further progress.

You must be aware that, although it may come into operation almost immediately, yet it may possibly not until some little time hence; but this is a question which now rests with others, and not so much with me, and we must not, therefore, be disappointed at some delay.

* * * * *

Your ever affect. son,

E. Davy.

We have arrived at the end of our MSS, and, consequently, at the end of our task, which, we need hardly say, has been to us a labour of love; but before laying down our pen we cannot resist the pleasure of quoting two short passages, which will serve to show in what estimation Mr. Davy was held by those most capable of comprehending his character. The first is from a Mr. Thomas Watson, London, a gentleman of great scientific attainments, to Davy's father:—

May 20, 1839.

My Dear Sir: I have to apologise for not acknowledging the receipt of your kind present ere this, an exceeding pressure of business must plead my excuse.

Permit me to say that any service I may have rendered your son has been to me a source of much gratification. I much regret, upon private grounds, that by his absence I lose an acquaintance which I highly prized, while, upon public grounds, science has lost an adjunct as talented as zealous, and, without flattery, I must add *his pursuits would have so enlightened and benefited his countrymen that his secession to the primitive shores of South Australia must be deplored as a national calamity.*

* * * * *

Believe me yours sincerely,

Thos. Watson.

The next extract is from a letter (October 21, 1839), of Charles Pain, the family solicitor, of Surrey-street, Strand, to the same address:—

"Mr. Carpmael passed some high encomiums on your son's talents in matters of science, and said he considered *his leaving England a great loss to the country*, and he particularly regrets his absence on account of the telegraph, which, had he been present, he would have had no difficulty in disposing of to the Great Western Railway Company, who are now adopting that of Messrs. Cooke and Wheatstone, and to whose, he says, your son's is very superior"

The rest can be told in a few words. For a year or two after Davy's departure for Australia, his father and one or two friends tried, but in a half-hearted way, to carry on the negotiations from the point where he himself had left them. Another exhibition of both the screen and recording telegraphs was opened in Exeter Hall for a few months in 1839-40, but, as those in charge of the instruments did not thoroughly understand them, and could not always get them to work satisfactorily, no good came of it.

The machines were sent down to Ottery St Mary at the end of 1840, and were stowed away in an out-house as so much rubbish. In the hope of rescuing them we lately paid a visit to Davy's native place, but found, to our grief, that only three years ago, on a change of residence, they were broken up and sold as old metal! Our informant, the family gardener, added "'twas such a pity, as there was as much mechanism about them as would fit up a hundred clocks!"

In a field we found some pieces of cotton-covered iron and copper wire, and six of the Daniell cells—huge things of three or four gallon-capacity. The outer jars are of glazed earthenware about eighteen inches high, and the porous pots are more than half an inch thick! These relics will now be carefully preserved.

And so ends the story of a *magnificent failure.*

Overhead Wires.—"Perhaps we had better not be in too great a hurry after all," says the *Globe*, "to get rid of the overhead telegraph wires. If they are a source of danger in one direction, they may, if the President of the Society of Telegraph Engineers and Electricians is not mistaken, conduce to our safety in another. It is not only Colonel Webber's opinion, but, according to the *Globe*, seems to have been that of the majority of those who attended the Electrical Congress at Paris in 1881, that the overhead wires may have the effect of dispersing electrical tensions above them, and, further, if a discharge takes place, may interrupt and convey it away. They may unfortunately carry it a long way, and with disastrous results. Colonel Webber has seen a man at work among telegraph wires thrown to the ground by a lightning shock from a storm twenty miles off. At the time he was struck there was not a cloud above them." For our part we do not see that it matters much whether the wires carry the lightning far or near, and the inference to be drawn from Colonel Webber's own illustration is rather against having wires very near you during a thunderstorm. The *Globe* should have spoken of Colonel Webber as a past president of the Society; but these little slips are to be expected.

THE ELECTRIC LIGHTING PROVISIONAL ORDERS.

Disappointing and inconvenient as it undoubtedly was, the result of the recent debate on the Electric Lighting Provisional Order for the parish of St. James is not greatly to be wondered at. Mr. Chamberlain had himself raised the spectre of monopoly in the early stages of the Electric Lighting Bill, and had kept it above ground all through the discussion. When, therefore, the provisions came to be applied to a particular case his political opponents, as well as the opponents of electric lighting in general, combined to frighten him with his own ghost. This is really the explanation of the wrangle over the question whether the committees to which the confirming Bills are to be referred should be empowered to hear parties against the Bills irrespective of their *locus standi.* The astonishing zeal in the affairs of a West End parish, and the anxiety to prevent a monopoly displayed by persons not usually supposed to be averse to the principles of monopoly, admit only of one explanation, namely, that the President of the Board of Trade having furnished the rope, there were plenty of people only too delighted to hang him with it. Mr. Chamberlain refused to be hanged; he yielded instead.

The consequence of this discreet though inconsistent surrender on the part of the Board of Trade is that parties may, and probably will, be heard in opposition to every confirming Bill presented to a parliamentary committee. These parties will represent interests of various kinds; first, the local inhabitants may appear over the heads of their duly elected local vestries; next there will appear the parties representing, indirectly of course, the gas interests; thirdly, there is the Metropolitan Board, which assumes to represent everybody; and lastly, there are the competing electric lighting companies, some of whom, strange to say, are ready to upset a settlement made with one company in order that a cheaper one may be entered into with themselves. This it will be said is competition carried to the utmost limits of freedom; but Mr. Chamberlain, being pledged to free competition, and sworn to prevent monopoly, was finally compelled to agree to let the parties be heard. There was no gainsaying the logic of the suggestion, if the logic on which he had argued the original Bill was sound. It was in a spirit highly hostile to monopoly that the measure was forced through Parliament, and a mere counterfeit of the same spirit threatens to wreck the measure.

We never cordially approved of the original Bill, but for once we are able to agree with the parent of it, who now finds that unreasonable uses have been made of his favourite arguments. He urges, and very properly urges, that to admit a competing company as petitioner against another company already in possession, and requiring only a confirming order, is practically to re-open the whole question, and in fact to set no limits to the obstruction of petitioners. It is a pity he did not see this before. In this way, said Mr. Chamberlain, they might go on hearing objections as long as there were any promoters, speculative or not speculative, offering to do the work more cheaply. The difficulty of making choice was what we foresaw from the very first, and it is one that could only be settled by free competition in the first instance untrammelled by any provisions against a possibly resulting monopoly. Mr. Chamberlain ought by this time to know perfectly well that none but speculative promoters would risk very much where a practical monopoly is not well nigh certain. If that is denied, then the legitimate reward of successful merit is withheld, and except for experimental purposes the really meritorious systems will not compete at all.

As to the action of the Metropolitan Board, it is as mysterious as the inaction of the Public Prosecutor. The last named personage has a soul, whereas boards are commonly said to have none. Perhaps that is the reason the one is willing to rest in contented obscurity whilst the other is always fussily anxious to prove its vitality. The Metropolitan Board, at all events, can have no other rational motive for interfering between the local authorities and the promoters whom they have chosen to light their districts. Of course, there is the well worn plea that the vestries are in danger of conferring a monopoly. With the experience the Board has had of raising loans one would have thought it might have learnt by this time that, except for the support of *monopolies,* open or disguised, loans would be very difficult to obtain.

Digitized by Google

Whatever may be the motive of its interference in this matter, whether to prevent fresh monopolies or to protect those already existing, the effect will be to delay the progress of electric lighting, and possibly to prevent its legal standing being confirmed in this present Session altogether. Most of the newspapers commenting on the interference of petitioners led by the Metropolitan Board seem to anticipate this result, and to deplore it. We, for our part, while we regret the delay, see in it only a fresh proof of the radical defect of the original measure, a measure that was carried in haste, but may be amended at leisure.

Since writing the above paragraph we learn that the Metropolitan Board of Works have withdrawn the whole of their petitions, and will not appear in any way before the hybrid committee. We are glad to welcome this complete change of front, even at the eleventh hour, but it cannot be forgotten that the opposition of the Board has greatly stimulated other opposition. Electric light engineers know that the greater part of the opposition is directly and indirectly from the holders of a gigantic monopoly—that of gas. It is no secret that money is being lavishly expended to further the ends of the monopoly, and to wreck the progress of the electric light. We do not believe that the attempt will be successful, nor do we think the gas interests will gain any credit at the conclusion of the contest.

CORRESPONDENCE.

MEDICAL ELECTRICITY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Reading the correspondence lately published on the above subject, and having had some practical experience in this direction, I beg to say a few words in favour of electricity as a curative agent in many cases, if properly applied. Most of the systems in use do not have the desired effect; they simply excite a few muscles, but do not penetrate deep enough into the internal parts of the body to cause a destruction and restoration of the equilibrium of the nervous, muscular, and other fibres. We know the most important parts of the body consist of capillary actions, and if some of these capillary tubes become stopped or choked up by foreign matter the result is illness in some form or other. We all know the action of electricity on capillary tubes; how beautifully it causes each molecule of conducting matter to repel each other, which gives us direct motion in the capillary tubes, a motion which could not be obtained by any other means so quickly. I cannot think we get this effect by the use of a coil or magneto machine applied externally. This method may be beneficial if the complaint or disease is very near the surface, but it will not penetrate the internal parts of the body. What we must do is to cause a through action to all the working organs of the system, so as to clear and set to work parts that have become corroded or impregnated with some foreign matter decomposed. This matter, set it free, and it will work out of the system through the blood, skin, &c. In cases of gout, paralysis, rheumatism, sciatica, nervous debility, and many other complaints, relief is the rule, not the exception. The only way of using electricity as a curative agent is by means of the electric bath. I say this, as it is by the use of these baths I have seen some good work done. I have seen neuralgia, toothache, cramp, fits, and similar temporary and local pains relieved by the external application of coil or machine, but I have not known this external application of the coil to give speedy relief or cure a long standing gout, rheumatism, lumbago, or do any good work in liver complaints, paralysis, or give speedy relief in cases of prolonged, or suppressed, condition peculiar to females, that the continued use of the electric bath will give in almost every case, and sometimes effectually cure. Some years ago I fitted up a number of these baths, and had every opportunity of watching the results, which I have done. There are two systems in use—one is known as Caplin's system; the other is known as Potin's system. Caplin's system is by the use of batteries alone, and a copper bath in which sulphuric acid and water is used. The patient lies on a wood frame, to keep him from contact with the bath, which is the negative pole; a brass rod is grasped by both hands outside the bath. This is the positive pole. The battery consists of from 10 to 30 one gallon cells. The elements are carbon and zinc, arranged as in Smee's cells, the electrolyte sulphuric acid one to seven of water. The batteries are fitted with a winding arrangement for lifting the plates out of the solution. Other forms of cells are used, but this form is preferred on account of the large quantity of current obtained. Potin's system is on a different principle. It is with this system I have seen some very good results obtained; this system was very successfully used by M. Adolphus (now deceased) in the West End for some years. The bath in this case is of slate, or some non-conducting material. Water is used as in the ordinary warm bath; the addition of some sea or bay salt is good. A coil is used with this system, which is a primary one of large capacity; the coil is wound with 10lbs. of No. 8 or 10 cotton covered wire. It has the ordinary contact breaker at the end of the bundle, and brass sliding tube to regulate the intensity. The battery consists of a one gallon cell; the elements are a prism of carbon in a porous pot, and a cylinder of zinc, the electrolyte a weak solution of bichromate of potass and sulphuric acid. Instruments or conductors are used for some complaints. As a rule the current enters at the head, or back, of the bath, and returns from the foot. These baths are very pleasant and refreshing if the current is not too strong. It is recommended that the patient should take at least 12 baths, as it sometimes happens that the first few baths develop up the complaint, and the patient is slightly worse, but the continued use of the baths will give relief, and very often effect a cure of many diseases. I shall be happy to forward further particulars or drawings of these baths.—Yours, &c., H. A. Kent.

154, Culford-road, N., July 14, 1883.

PROVISIONAL PROTECTION.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: It appears that the period of provisional protection in the forthcoming Patent Amendment Act is to be extended to twelve months. This, in my opinion, will be adding six months of anxiety to the present unsatisfactory arrangement experienced by inventors, especially by those of limited means.

The amount of systematic dodging and organised swindling that the so-called provisional protection admits of is too well known already. The poor inventor would stand much less risk if the law necessitated the filing of a complete specification, and so settle the matter at once.

On scientific and legal grounds discoveries and inventions should be clearly defined at the date of filing, so as to leave no doubt as to who is the first in the field. What right, I would ask, has an inventor to apply for a patent for an invention before he is able to define the novelty of the particular machine forming the subject matter of his application? A, a capitalist, might file an application for improvements, &c., in certain apparatus. B, an inventor, might also do the same a few days after A, for improvements in the same direction, but essentially different from A's invention. As B would probably require assistance in the development of his invention, he might go to A, and the latter might, with the aid of skilful assistance, include the invention of B in his own final specification, and so claim priority. It is true that the final specification is supposed to be substantially the same as the provisional; but that is a matter that would have to be decided in a court of law, when B, having no capital, would, I am afraid, stand a very poor chance.

Provisional protection suits the well-to-do manufacturer

Digitized by Google

and "adapter" rather than the "first and true inventor," whilst it is a powerful weapon in the hands of the unscrupulous.—Yours, &c., INVENTOR.

THE GRAMME RING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On referring to Mr. Mordey's letter in *The Electrician* for May 5, I find that (for some reason unknown to me) I *had* misread the latter part of his communication. Had I referred to your publication at the time of writing the mistake would not have occurred.

Mr. Mordey says:—"I found that with four poles the product of current and E.M.F. in the external circuit was a *little more than* 100 per cent. greater than when two poles were employed." This means an increase of about 45 per cent. only in the E.M.F.!

It may be worth noticing that in a Gramme ring of ordinary construction, the thickness of wire on the outside is much less than would obtain if the same wire were put on to a flat core of the same mass and sectional area, and consequently the field magnets may be considerably nearer the iron, a condition obviously favourable to induction from one side.—Yours, &c., W. B. SAYERS.

Cambridge-street Works, Birmingham, July 17.

PRACTICAL TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of June 16th I see in the article on "Practical Telephony," page 114, the action of the telephone described thus:—"The action of the telephone depends on the well known principle that when a coil of insulated wire is placed on the end of a permanent magnet, or its soft iron pole piece, any movement to or from the pole piece of an iron armature induces a current in the coil of wire. . . . . If the diaphragm be spoken against it vibrates in unison with the voice, and as the diaphragm is the armature of the magnet, corresponding undulating currents are generated in the coil of wire surrounding the magnet." My understanding of the action is, that the vibration of the diaphragm *does not induce a current in the coil by its vibration*, but modifies or regulates the flow of the current by its approach to or recedence from the core.

Having only crude instruments to experiment with I cannot get as good results as if I had perfected ones to work with. The experiment I made to demonstrate my theory on the telephone current was made by using one Bell magnetic telephone and ordinary telegraph key; the terminals of the telephone were grounded in a moist clay soil 60ft. apart with key inserted between one terminal and ground wire. When the key was pressed down I could hear a click, caused by the diaphragm being attracted by the core, and on opening the key could hear a click caused by the diaphragm springing back to its normal position. This convinced me that there was a current at all times not caused by the vibration of the diaphragm, the current commencing as soon as the magnet pole was surrounded by insulated coil of wire an induced current of uniform flow, *but made undulating* by vibration of the diaphragm when used as a transmitter. I thought at first that the current might have been caused by a difference of potential at the grounding, but an electrician informed me that that was too small a distance to get a difference in.

If I am mistaken in my theory will some reader please carry out the experiment, and inform me through the columns of *The Electrician* the result.—Yours, &c.,

Bryan, O., July 5, 1883. W. E. KAUKE.

MANCE'S METHOD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to the note on Mance's battery test in your last issue, let me point out a slight error occurring in Mr. Barker's last calculation, not, however, interfering with the proof. The total deflection (596·16) should be divided by the ratio $\frac{19{\cdot}09}{10}$ instead of $\frac{19{\cdot}09}{9{\cdot}09}$ to obtain the galvanometer deflection when they closed, which is, therefore, 312·3 divisions.—Yours, &c., H. D. WILKINSON.

School Electrical Engineering,
12, Princes-street, Hanover-square, W., July 16, 1883.

NOTE ON CURRENT ENERGY, &c.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To Mr. Heaviside's admirably simple and elegant discussion of the relations between E.M.F. and current vectors let me add a very simple little result as a corollary. In the case of any conducting medium, if the E.M.F. vectors corresponding to current vectors in any three rectangular directions are coplanar, the E.M.F. vectors corresponding to currents in *all* directions will be in the plane of the first three.

If η be the E.M.F. vector corresponding to the current vector ω, the general relation between these is,

$$\eta = -\eta_1 S\, i\,\omega - \eta_2 S\, j\,\omega - \eta_3 S\, k\,\omega,$$

or

$$\eta = \chi\,\omega,$$

where χ is a linear vector (but not self-conjugate) function, and (i, j, k) are rectangular unit vectors, while η_1, η_2, η_3 are constant vectors. Operating on this equation successively with $SV\eta_2\eta_3$, $SV\eta_3\eta_1$, $SV\eta_1\eta_2$, we find that, if $S\eta_1\eta_2\eta_3=0$, η must tie in the plane of $\eta_1\eta_2\eta_3$. In general

$$\omega = \frac{1}{S\eta_1\eta_2\eta_3}(i\,S\eta_2\eta_3\eta + j\,S\eta_3\eta_1\eta + k\,S\eta_1\eta_2\eta),$$

which deduces the current from the E.M.F. vector.

Mr. Heaviside then goes into matters which, though not deducible from the equations of the subject, possess a strong interest, at any rate for me. The design argument can be vastly extended and illustrated in even pure mathematics, just as Mr. Heaviside (to whom, therefore, the theologians are deeply indebted) has shown that it can be in the consideration of Ohm's law, and the fearful consequences which would result from its invalidity.

Mr. Heaviside (no doubt with recollections of *Patience*) says, "Conceive, then, if you can, the electric light young man." I can conceive him, but I prefer at present to refer to an archbishop, who two or three years ago delivered to his clergy a charge which was meant to be a supreme criticism of science based on the most authoritative knowledge, to assure his clergy and the public in general that the heads of the Church kept pace with the foremost scientific ideas. There was, however, a poverty of illustration, at least in the electrical department of the charge; for the archbishop, mounting to the summit of eloquence and scientific knowledge, exclaimed, "I may admire your electroscope as a scientific wonder, but beyond it there is something," &c., &c.

If bishops and archbishops take Mr. Heaviside's hint, they can compose magnificent charges with very little trouble by taking up a few of the less known laws and facts of science—say conical refraction and the law of Lenz—in the way pointed out by Mr. Heaviside. Electroscopes are, no doubt, mighty instruments in the hands of science, but they are not now sufficiently impressive; for it is possible that even some school girls may be present who will recognise the name when it is trotted out for effect.

GEORGE M. MINCHIN.

R. I. E. College, Cooper's Hill, July 18, 1383.

INTERNATIONAL FISHERIES EXHIBITION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: No practical man who has seen the electric machinery at work at the International Fisheries Exhibition but has been struck by the terrible overloading of the engines. A breakdown more or less serious is at any time not only a possibility, but is *inevitable*. It is then the usual cry will be raised, "Oh! the electric light is not to be depended on,"

Digitized by Google

and by the general public the *light* will be condemned, while the real fault lies at the door of the engineers. Already your contemporary the *Engineer* (in its issue of 22nd June) has saddled the wrong horse. "The *electricians*," it says, "have, *as usual*, underrated the power required to drive their machinery." Note the "as usual," and be sure that at the first serious breakdown there will be a chorus of, "We told you so" from the real culprits.

The old time remedies have been tried—heavy belts, regardless of cost, and these tightened up till life and limb are seriously endangered. Already, not once or twice, but half a dozen times, the over-stretched belts have given way, and where they do not give way the whole time of the engine drivers is devoted to keeping the shafting cool. It is under these circumstances that I have made an offer to the Exhibition Committee, and to the engineers an offer that I now repeat, and it is this: I will prove and demonstrate that the electricians have *not* underrated the power required, but that the power that is now being lost or wasted through defective transmission is more than sufficient to actuate the whole of the dynamos without tightening the belts and without overworking the engines as they are now overworked, at the momentary risk of a grand breakdown, to the prejudice of the electric light. In other words I will save power or increase the efficiency of the motors to the extent of at least 25 per cent. I propose to do this by the application of Samper's patent pulley grippers, which I will put on and take off again *without charge* if they fail to accomplish what I have undertaken, but for which I ask *net cost price* if they succeed.

Says Mr. Paxman to me to-day, "If you can do that I will give you the whole of this installation of engines and boilers; but the principle of your system is old and well known, and is nothing but a belt tightener, and would actually load my engines more than ever." Now, with the gripper I work with *looser* belts than any other sytem, and I have illustrated this on Messrs. Davey, Paxman, and Co.'s own engines at the Crystal Palace. I hold the testimonial of Mr. Brockie, of the British Electric Light Company, who says: "Before the application of the gripper we were much troubled with hot bearings. With the gripper this was *entirely obviated*." "Still," says Mr. Paxman," it looks like a belt tightener, and so it must be one." Now, on the other side of the water, where I come from, when we find a man persisting in a wrong-headed opinion, we ask him at what he values his opinion in dollars. And I would ask Mr. Paxman "how many dollars will you go that I do not save, as I have offered, at least 25 per cent. of power on the Fisheries installations?" I do not want to hold him to his word as to the princely offer he made me of his engines and boilers, but I do want a fair field and no favour in demonstrating that, by the simple and comparatively inexpensive means I have offered to employ, the electric light at the Fisheries can be saved from the great danger of disastrous collapse that now threatens it.

I address myself to you because the province of your journal is to protect the interests of electricians, and to see that the faults of others are not fathered upon them.—

Yours, &c., M. F. Adams.

London, July 18, 1883.

AN ELECTRICAL STEAM LAUNCH.

On Tuesday an experimental trip was made with a launch built by Messrs. Yarrow and Co., of Poplar, of galvanised steel 40ft. in length, and propelled by a Siemens dynamo placed at the stern under the floor, which drives a screw propeller direct. The electricity for giving motion to the dynamo is obtained from Faure-Sellon-Volckmar accumulators placed under the floor of the boat, so that they are quite invisible, and occupy no space that would be available for passenger accommodation. In this respect the electrical system will be seen to have a very great advantage over steam, as in a launch of these dimensions at least 11ft. of the central and best part of the boat would be occupied by the boiler and engines. Consequently, in comparing launches propelled by steam or electricity, it must be borne in mind that the passenger-carrying accommodation for the same dimensions is much greater in the electrically-propelled boat. The run from the Temple Pier to Greenwich was made in thirty-seven minutes with a moderate tide. The distance is six miles, so that, making allowance for the tide, it may be said that a speed of over seven miles an hour was attained, and full power was not employed save for a portion of the time. On the measured mile an average speed of over eight miles an hour has been obtained.

The boat had twenty-one persons on board, including the steersman and a man to look after the machinery, if such it may be called. Eighty cells of Sellon-Volckmar accumulators are used, of which fourteen are disposed under the seats, seven at each side, and the remainder in the bottom of the boat under the floor. The thrust block is just aft of the dynamo, which is placed under the floor in the stern sheets. It lies flat, and occupies very little space. There are four brushes, two for going ahead, two for going astern, and two small lines going to a becket beside the steersman enable him at a moment's notice, by pulling one or the other, to go ahead or astern; a cylindrical switch beside him enables him to stop or go on at pleasure. This switch is graduated so that the current from forty, sixty, or eighty cells can be used at pleasure. The weight of the whole—batteries and dynamo—is about two tons, or as nearly as possible that of engine, boiler with water, and coal for a steam engine competent to propel her at the same speed.

This pretty launch is the very perfection of a pleasure boat; no heat, no smoke, no dust, no steam, no smell of oil, no splashing of pumps. There is no noise of any kind to be heard save the bubbling of the water from the propeller, and the faint hiss caused by the commutator rubbing against the brushes. There is no smell, and there are no furnaces; and the boat will run for six hours continuously, or about forty miles.

During the trip to which we are referring the current passed through the dynamo was 41·22 amperes from sixty cells, the electromotive force being 112·5 volts, and $\frac{41{\cdot}22 \times 112{\cdot}5}{746}$ = 6·21 horse-power. The loss by friction, &c., must be very small, for 6 indicated horse-power could certainly not have propelled the boat at the speed she really attained. It has long been known that the screw is an extremely wasteful propeller. It may yet be that further investigations will show that the screw is not so much to blame as the combination of screw and engines. At any rate the system of electrical propulsion opens up a new field of inquiry, because it renders possible the use of screws of extremely fine pitch revolving at a great speed. The dynamo in Mr. Yarrow's boat makes about 680 revolutions per minute. The propeller is of steel, two bladed, 19in. diameter, and 13in. pitch. There is absolutely no vibration, and very little disturbance of the water in the wake of the boat.

For such work as that now done by steam launches on the Thames, the electrical system is simply perfection. The expense will be, on the whole, about that of steam, but to those who keep steam launches expense is a secondary consideration, and it must not be forgotten that a 20ft. electrical launch will afford at least as much accommodation as a 30ft. steam launch. Little difficulty should be encountered in charging the cells, and this is merely a question of detail.

After the cells are once stored with electricity they will remain so for a considerable time, subject only to a diminution through leakage; consequently a boat once charged is available for use at a moment's notice, while with a steam launch it is necessary to give one or two hours' notice before hand in order to get up steam.

The Western and Brazilian Telegraph Company.—The traffic receipts for the week ending 13th July were £1,853, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRIC LIGHTING (HOLBORN VIADUCT).

The following is Mr. W. Haywood's report to the Streets Committee of the Commissioners of Sewers:—"The experimental electric lighting of the Holborn-viaduct with Edison's incandescent lamps having been in operation for a period of twelve months on the 24th April last, I have to report the general facts relating to the experiment. On the 29th October, 1881, application was made by the Edison Electric Light Company for permission to light the public ways of the Holborn-viaduct with Edison's incandescent lamps. Permission was granted by the commission, and an agreement entered into on the 2nd January, 1882, Mr. Johnson, the manager, undertaking on the part of the company to light the viaduct for three months, between the 1st February and the 30th April, 1882, free of cost to the commission. At the time this agreement was entered into it was understood that the Edison Company would not be interfered with by the commission if they introduced their system of incandescent lighting into the premises upon the viaduct, although the commission gave, and could give, no authority for this being done. Owing to various circumstances the lighting of the viaduct was not commenced until the 24th April, 1882. It was then in thorough working order, and the ordinary gas lighting was dispensed with. The lighting having been in operation for a period of three months on the 24th July, 1882, the Edison Company applied to the commission to have the experiment extended for a further period of six months from the date named, upon the commission paying the same amount for electric lighting they would have had to pay for the ordinary gas lighting during that period. This was agreed to, and the lighting was continued until the 24th January of the present year. Subsequently it was agreed that the contract should be extended for a further term of twelve months from the 24th January of the present year, upon similar conditions, that is to say, at the price of the ordinary gas lighting, the commission reserving to itself the right of determining the contract upon its giving ninety days' notice of its intention to do so. The viaduct is now lighted on these conditions. The viaduct had, therefore, been lighted by the Edison Company for a period of twelve months on 24th April last. It is to that period my report applies, and following the course adopted in previous reports on the various systems of electric lighting in the City, I now give some details of the incandescent lighting. The machinery for generating the electric current is fitted up in the basement of No. 57 on the Holborn-viaduct, the premises are on the northern side of the way, between Farringdon-street Bridge and the Snow-hill Station of the London, Chatham, and Dover Railway. The company has also used other premises in the rear of No. 35, Snow-hill for the purpose of the experiment. The machinery for generating the electric current is of a novel character, and is stated to have been specially designed by Mr. Edison. There are two of Edison's dynamo machines, each worked by a Porter-Allen direct driving engine capable of working to 140 horse-power indicated. One dynamo can sustain 1,000 lamps, the other 1,200 lamps of 16 candle-power each. In addition to the two, a third 1,200 light dynamo, fitted with a similar engine, has been erected in the company's premises at the rear of No 35, Snow-hill; this is now at work. A 250 light dynamo, driven by an Armington and Sims engine, has also been placed in position, and is being used for supplying electrical current to such consumers as may require light during the daytime. All these particulars are supplied me by the Edison Company. From the dynamos the conductors were laid direct into the subways beneath the viaduct, an opening having been made from the house vault of No. 57 into the subway for that purpose. The main conductors are formed of solid copper rods, semicircular in section, embedded in an insulating material and enclosed in wrought-iron pipes; these are laid upon the brackets in the subways, provided there for similar purposes when the subways were built. From the main conductors the connections with the public lamps and with private premises were made by means of insulated cables and wires. Where the conductors pass beneath the Farringdon-street and Shoe-lane bridges, they are suspended from the girders. Owing to the contiguity of the house vaults to the subways which exist beneath the footways on each side of the Holborn-viaduct, the main conductors and the various connections with the lamps and premises upon the line of the viaduct were made without disturbing the surface of the public ways. In fact, it has not been found necessary to make any opening upon the surface of the viaduct for the purpose of the experiment. The electric lamps used are those known as Edison's incandescent lamps, and consist of pear-shaped glass globes containing thin loops or filaments of carbon in vacuo, heated to a state of incandescence when the electric current is passed through them. The number of incandescent lamps in use for lighting the public way when the experiment first commenced was 176—of which 156 were each of 16 candle-power, and 20 each of 8 candle-power—two 16 candle-power lamps were placed in the majority of the ordinary gas lanterns, and several groups of eight 8-candle lamps were placed in the lanterns at other places. This arrangement was modified towards the end of August last, the two incandescent lamps in each gas lantern were removed, and one lamp (said to be equal to about 16 candles) was placed in each of the ordinary gas lanterns. The lamps on the five-light column at the eastern end of the viaduct, and on that at the junction of the viaduct and Snow-hill, were also removed, and large lanterns, octagonal on plan, each enclosing eight incandescent lamps, were placed in them. Each incandescent lamp is said to have been equal to 16 candle-power. These lanterns were fitted with reflectors for throwing down the light on to the public way. On the four public staircases leading from the viaduct to Farringdon-street the incandescent lamps were not enclosed in the ordinary gas lanterns, but were suspended outside the lamps. Each had 16 candle-power. With the exception of those on the five-light columns referred to, the existing lanterns and posts were utilised for fixing the incandescent lamps. The gas fittings were not removed; the incandescent lamps were made movable, the connecting wires being taken from the subways through the bases of the lamps to the lanterns in lengths of gas tubing. This arrangement enabled the incandescent lamps to be removed, and the gas to be immediately lighted in the event of a failure in the electric light. The total number of incandescent lamps in use during the latter part of the experiment, or, as it may be said, when the experiment was in complete operation, and as at the present time, is as follows:—

	Lamps of 16 c.-p. each.
In the ordinary gas lamps on the viaduct and those around the Prince Consort's Memorial.........	64
On the five-light column at the eastern end of the viaduct and at Snow Hill	16
On the staircase buildings............	12
Total............................ ..	—92

[I am informed by the company that the total number of incandescent lamps on the line of the viaduct, in use in private premises, and maintained from their works, is about 745.] The total length of thoroughfare lighted is about 466 yards, and the superficial area about 12,400 yards; each incandescent lamp upon the viaduct illuminates an area of about 155 yards superficial. The illuminating power of each of the incandescent lamps in use since August is stated by the company to be about 16 candles. No photometrical observations to test the accuracy of this statement have been made by the officers of the commission. The number of gas lamps disused while this experiment has been in operation is 86. Each of these is fitted with a batswing burner, consuming five cubic feet of gas per hour, the illuminating power of which is customarily estimated at about 14 candles each. The relative illuminating power of the Edison incandescent lamps and of the gas lamps is therefore as follows:—

	Candles.
92 incandescent lamps, say at 16 candles each........................	= 1,472
86 ordinary gas lamps, at 14 candles each........................	= 1,204

Digitized by Google

The illuminating power of the incandescent lamps is therefore about 1·22, or say $1\frac{1}{4}$ times as much as that of the ordinary gas lamps. The cost of the gas lighting on the viaduct at the present contract price to the commission would be £388 8s. 8d. per annum, and the Edison Company light the viaduct for that price. This is at the rate of £4 10s. 4d. per lamp per annum. Thus the illuminating power of the electric light is about $1\frac{1}{4}$ times that of the ordinary gas lighting, and at the same cost as gas lighting. As at other places when experiments in lighting have been in operation in the City of London, arrangements were made with the police for carefully noting defects. Reports were furnished to me daily by Colonel Fraser, giving the situations of the defective lamps, and the time the defects existed. These were sent to the Edison Company, who returned them to me with such explanations or remarks as they thought necessary to make as to the cause of the failure in the lighting. Considering it essential for the commission to have before it a complete account of these defects, a list of them is given in the Appendix. The extent and nature of these failures may briefly be stated as follows:—There were for the first portion of the experiment, until the end of August last, 176 incandescent lamps in operation, that is two lamps in the majority of the 86 gas lanterns, and several groups of eight lamps, each assumed to be alight 1,052 hours from the 24th April to that date, which is equivalent to 185,152 hours lighting of a single lamp. There were 92 incandescent lamps in operation for the remainder of the twelve months, each assumed to be alight 3,228 hours, which is equivalent to 296,976 hours lighting of a single lamp. These together are equal to a total of 482,128 hours lighting of a single lamp. The total number of failures in the lighting from all causes was 815, counting every failure each night separately; their aggregate duration was equal to 1,515 hours of a single lamp, or about ·03 per cent. of the entire lighting for the twelve months. It may be said broadly that a defect of longer or shorter duration occurred in something like 1·17 lamps nightly out of the 176 lamps lighted in the first portion of the year, and 2·80 lamps nightly out of the 92 lamps lighted during the remainder of the year. The principal failures appear to have arisen from defects in the machinery, and many from defective carbons in the incandescent lamps. This was the first experiment in the metropolis in lighting a public thoroughfare with incandescent lamps, all previous experiments having been made with arc lamps of large illuminating power placed at considerable intervals apart. The arc system may be suitable for lighting large open spaces, and from the intensity of its light, which dazzles the eye, it receives a large amount of public attention. But the perfection of public lighting consists in the equal distribution of light over the surface of the streets, and this the arc light does not accomplish. If the arc lights be reduced in power, their number increased, and the distance between them diminished, the objection to them would of course be less, but, unless this be done, it is not so good a mode of lighting the public ways as either gas light or the incandescent light. The Holborn-viaduct is a favourable situation for the trial of incandescent lights, it being a thoroughfare of regular width, and on which the gas lamps are placed at regular intervals apart, no lamp being more than 60 feet from the next one, and the diffusion of light, whether gas or the incandescent light be employed, provided that all the lamps are lighted, is better and more uniform than in most of the thoroughfares of irregular width in the City. It should be mentioned with respect to this incandescent lighting, that it has been subject to a somewhat unfortunate comparison with the gas lighting next to it; for whilst it has been in operation, the whole length of that portion of Holborn which is within the City, and is to the west of the viaduct, has been lighted with Siemens's regenerative gas burners, and the large five-light lamp column at the western end of Newgate-street has also been lighted with a similar burner; the lamps in Holborn are almost as close together as the lamps on the Holborn-viaduct, and have each a nominal light of 130 candles, whilst that in Newgate-street had a light of 400 candles. These Siemens lamps, which cost about £17 5s. per annum to light and maintain, have been naturally put into comparison with the Edison incandescent lamps costing but £4 10s. 4d. per annum to light and maintain. The contrast between gas lamps of 130 candle-power and incandescent lights of 16 candle-power has been necessarily greatly to the detriment of the incandescent lamps, and this has been much remarked upon by persons unacquainted with the facts. The Siemens lamps have just been removed; a comparison with ordinary gas lamps will now be afforded, and conclusions as to the value of the Edison incandescent light, compared with the ordinary gas lighting of the City, can now be more correctly arrived at."

ON THE CHEMICAL CORROSION OF CATHODES.*

BY G. GORE, LL.D., F.R.S.

(CONCLUDED FROM PAGE 215.)

Experiment 10.—A trial was made to find whether two plates of pure silver cut from contiguous parts of the same piece, and then carefully cleaned by rubbing with a rag dipped in potassic cyanide solution, and immersing first in cold and then in boiling distilled water, and drying, were corroded at the same rate. The corroding solution consisted of 50 grains of potassic cyanide (sample "b") in each ounce of water. The plates were immersed in precisely similar positions during four hours at atmospheric temperature.

Plate A lost	·391 =	·0977	grain per hour.
Plate B lost............	·389 =	·0972	" "
Difference	·002 =	·0005	" "
After two hours' further action			
Plate A lost	·296 =	·1480	grain per hour.
Plate B lost............	·271 =	·1355	" "
Difference	·025 =	·0125	" "
After another two hours			
Plate A lost	·248 =	·1240	grain per hour.
Plate B lost............	·253 =	·1265	" "
Difference	·005 =	·0025	" "

Remarks.—These results again show the difficulty of obtaining plates which are equally corroded.

The presence in the liquid, even in minute amount, of certain kinds of dissolved impurities, would distinctly affect the rate of corrosion; if the liquid contained only a mere trace of a salt of a more negative metal than that of the cathode it would be deposited upon the cathode, and thus form a voltaic pair, and increase the corrosion. Even with two pieces of the purest metal, immersed in the purest liquid, kept at the same temperature during the same length of time, and under apparently the same conditions in every respect, the same rates of corrosion could not be repeatedly obtained.

The altered chemical composition of the liquid around the cathode also, caused by substances set free or formed by electrolysis, affected the corrosion.

COMPOSITION OF THE LIQUID AROUND THE CATHODE.

Experiment 11.—In order to ascertain whether the protective effect of the current upon a silver cathode in a solution of potassic cyanide was due to some immediate influence of the current, or to the chemical effect of substances liberated or produced by electrolysis, four ounces of a solution containing 300 grains of potassic cyanide (sample "a") was put into a large U-shaped glass tube, and $1\frac{1}{2}$ ounce of the same liquid into a glass cup of the same diameter. An electric current from four Smee cells was passed, during nineteen hours, through the liquid in the tube by means of a sheet-iron anode and platinum cathode immersed about $2\frac{3}{4}$ inches. Gas was somewhat freely evolved at the cathode. The current was then stopped and the electrodes removed. Three perfectly similar plates of silver, one inch wide, were now suspended $2\frac{3}{8}$ inches deep in the three portions of liquid respectively of the two vessels, during several successive

periods of time, and weighed at the end of each period, no electric current being now employed. The losses were as follow:—

Hours.	In the Anode Liquid.		In the Cathode Liquid.		In the Comparison Liquid.	
	Loss.	Loss per hour.	Loss.	Loss per hour.	Loss	Loss per hour.
2	·158	·0790	·131	·0655	·170	·0850
2	·106	·0530	·155	·0775	·162	·0810
2	·139	·0695	·158	·0790	·178	·0890
15	1·023	·0682	1·101	·0734	1·259	·0839
21 Total.	1·426 Total.	·0674 Average.	1·545 Total.	·0738 Average.	1·769 Total.	·0847 Average.

Remarks and Conclusions.—The average corrosion of the silver in the anode liquid was to that in the comparison one as 79·69 to 100, and the protective effect was, therefore, 20·31 per cent.; whilst that in the cathode liquid* was to that in the comparison one as 87·13 to 100, and the protective effect 12·87 per cent.; or for the first hour alone it was 22·94 per cent.† These numbers show clearly that electrolysis of the liquid produced such an alteration in the chemical composition of the portion of it around the cathode as to largely reduce its subsequent corrosive action upon silver. The protective influence, therefore, of an electric current upon a silver cathode in a solution of potassic cyanide is at least partly due to chemical changes produced in the liquid by electrolysis—*i.e.*, to caustic potash formed at the cathode. In what way the cyanogen liberated and dissolved in the liquid around the anode diminishes the subsequent corrosion of the silver I have not examined. The irregularities in the variations of the numbers were probably in some degree due to changes of temperature. As after making various experiments it was found that an iron anode is slightly corroded in a solution of potassic cyanide, some of the numbers in the above table may be affected by that circumstance, but only to a minute extent.

Experiment 12.—In a similar experiment, $1\frac{1}{4}$ ounce of dilute sulphuric acid, consisting of three volumes of acid to ten of water, was placed in a narrow glass cup, four ounces of the same mixture were electrolysed in the bent glass tube of Experiment 11, by means of sheet platinum electrodes and a current from four Smee cells during $2\frac{1}{2}$ hours. Gas was freely evolved; the current was then stopped, and the electrodes removed. Three similar sheets of electro-copper were suspended in the three separate portions of liquid of the two vessels, and weighed at separate intervals of time. The following were the losses:—

Hours.	In the Anode Liquid.		In the Cathode Liquid.		In the Comparison Liquid.	
	Loss	Loss per hour.	Loss	Loss per hour.	Loss	Loss per hour.
2	·039	·0195	·010	·0050	·043	·0215
16	·102	·0063	·046	·0028	·144	·0090
2	·020	·0100	·012	·0060	·031	·0155
20 Total.	·161 Total.	·0119 Average.	·068 Total.	·0046 Average.	·218 Total.	·0153 Average.

Remarks and Conclusions.—The average corrosion of the copper in the anolyte was to that in the comparison liquid as 77·77 to 100, and the protective effect, therefore, 22·23 per cent., whilst that of the catolyte was 30·06 to 100, and the protective effect 69·94 per cent. As with silver in solution of potassic cyanide (sample "a,"—*see* Experiment 4), so in this liquid the electric current affected the chemical corrosion at *each* electrode, and the corrosion was in each case greater in the non-electrolysed than in either of the previously electrolysed portions of liquid. But in this experiment the subsequent protective effect was three times greater in the catolyte than in the anolyte portion of liquid. But few experiments were made with copper, partly on account of the frequent variations of weight caused by unequal oxidation.

The corrosive influence upon a silver cathode during electrolysis of a cyanide of potassium solution containing caustic potash produced by the electrolysis would probably be greater than that of a liquid of perfectly similar composition, but not undergoing electrolysis, because in the former case the liquid around the cathode would be stirred by the escaping hydrogen, whilst in the latter it would be much less in motion. Another influencing circumstance is, the potash resulting from electrolysis is produced in a layer all over the surface of the cathode, whilst that in the comparison liquid is distributed equally throughout the mass of solution. What the proportion of difference in the two cases is I have not examined.

Experiment 13.—To test in another manner the influence of alkalinity of the liquid upon the corrosion of silver, 300 grains of potassic cyanide (sample "a") were dissolved in six ounces, by measure, of water. The liquid divided into two equal volumes, and $1\frac{1}{2}$ grain of pure potassic hydrate dissolved in one of the portions. Two previously-weighed sheets of silver of the usual dimensions were each immersed $2\frac{3}{8}$ inches deep in the two liquids respectively during fifteen hours.

	Grain.		Grain.	
The sheet in the alkaline liquid lost	·963	or	·0642	per hour.
„ potassic cyanide alone	1·028	„	·0685	„

Proportion of loss, 93·7 to 100 = a protective effect of 6·3 p.c.

4·5 grains more potash were now added to the comparison liquid, and the plates re-immersed during six hours.

	Grain.		Grain.	
The plate in the alkaline liquid lost	·406	or	·0676	per hour.
„ potassic cyanide alone	·422	„	·0703	„

Proportion of loss, 96·2 to 100 = a protective influence of 3·8 per cent.

After a further forty hours of re-immersion

	Grains.		Grain.	
The plate in the alkaline liquid lost	2·332	or	·0583	per hour.
„ potassic cyanide alone	2·174	„	·0543	„

Proportion of loss, 107·2 to 100 = a corrosive influence of 7·2 per cent.

Remarks and Conclusions.—The protective effect in this case was much less than in the stronger solution of potassic cyanide (in Experiment 4), which had been previously electrolysed before immersing the silver. These results support in the main the conclusion that the protection afforded by an electric current entering a silver cathode from a solution of potassic cyanide is partly due to the formation of potassic hydrate by electrolysis at that electrode. But as the presence or addition of caustic potash only diminished the corrosion, whilst the electric current is capable of entirely preventing it, the current operates not only by producing potash at the cathode, but also in some other manner.

Experiment 14.—To further examine the influence of greater alkalinity of the liquid upon the corrosion of silver cathodes, 600 grains of potassic cyanide (sample "a") was dissolved in twelve ounces of water, the solution divided into two equal portions, and sixty grains of pure caustic potash dissolved in one portion. Each of these liquids, A and B, was divided into two equal parts, one of A and one of B being used as electrolytes, with an anode of platinum and cathode of silver, and the others as comparison liquids, with the usual sheets of silver immersed in them. A current from four Smee elements was passed through the two electrolytes arranged in single series during $41\frac{1}{2}$ hours at 52·2deg. Fahr.

In the Solution of Cyanide

	Grains.		Grain.	
The silver cathode lost	1·823	=	·0439	per hour.
„ comparison sheet lost ...	2·896	=	·0697	„

Proportion of loss, 63·25 to 100 = to a protective effect of 36·75 per cent.

* I have sometimes found it convenient to use the term *anolyte* and *catolyte* to designate respectively the portions of liquid which are in contact with and around the anode and cathode.

† The rates of corrosion during the first two hours afford another mode of comparison.

Digitized by Google

In the Solution of Cyanide and Potash

	Grain.		Grain.	
The silver cathode lost	2·094	=	·0504	per hour.
„ comparison sheet lost...	2·518	=	·0606	„

Proportion of loss, 83·16 to 100 = a protective effect of 16·84 per cent.

Remarks.—In this case the most alkaline liquid exercised the least protective influence upon the cathode, but greatest upon the comparison plate.

INFLUENCE OF TEMPERATURE.

Experiment 16.—With two pieces of silver in two portions of solution of potassic cyanide containing 25 grains per ounce, the amounts of corrosion at average temperature of 46·0deg. and 57·7deg. Fahr. were respectively ·558 grain and ·629 grain, or ·0757 and ·0798 grain per square inch per hour.

Experiment 17.—To find the influence of difference of temperature upon the rate of corrosion of a cathode, 120 grains of potassic cyanide (of 93·5 per cent.) were dissolved in twelve ounces of water, and the solution divided into four equal portions, two of which were kept at 71deg. Fahr., and the other two at 150deg. Fahr. Four similar sheets of pure silver two inches long and one inch wide were immersed vertically, each to a depth of two inches, in the several portions of liquid during five hours. An undivided current from six Smee cells was passed through the plates of one of the hot and one of the cold portions, the other two immersed plates without a current being used for purposes of comparison.

At 71*deg. Fahr.*

	Grain.		Grain.	
The cathode lost	·021	=	·0042	per hour.
The comparison sheet lost..	·213	=	·0426	„

At 150*deg. Fahr.*

	Grain.		Grain.	
The cathode lost	·016	=	·0032	per hour.
The comparison sheet lost.	·322	=	·0656	„

Remarks.—According to these results a current of equal strength exercised a greater protective power in the hot liquid than in the cold one; the corrosive power, without a current, was, as usual, much the strongest in the liquid of highest temperature.

Experiment 18.—To ascertain the influence of temperature on the corrosion of silver electrodes, and upon the deposition of silver in a solution composed of 180 grains of potassic cyanide (sample "a"), 300 grains of argentic cyanide, 36 grains of free potassic cyanide, and 12 ounces of water, the liquid was divided into four equal portions, two of them being for electrolysis, and two as comparison liquids containing similar sheets of silver. One of the comparison liquids and one of the electrolytes were kept at 63deg. Fahr., and the other two portions at 150deg. Fahr., in a water bath, and the loss by evaporation occasionally corrected by addition of water. The undivided electric current was from two Smee elements, and was continued during four hours.

At 63*deg. Fahr.*

	Grains.		Grains.	
The silver anode lost	19·779	=	4·9447	per hour.
„ cathode gained	19·253	=	4·8132	„
Difference	·526 grain.			
„ comparison sheet lost.	·239	=	·0597	„

At 150*deg. Fahr.*

	Grains.		Grains.	
The silver anode lost..............	20·539	=	5·1347	per hour.
„ cathode gained	19·228	=	4·8070	„
Difference	1·311 grain.			
„ comparison sheet lost.	·423	=	·1057	„

Remarks.—I have shown elsewhere ("The Electrolytic Balance of Chemical Corrosion,") that when a current is passing into a silver cathode from a solution of potassic cyanide containing a very small amount of argentic cyanide, and the density (or strength per unit of surface) of the current is gradually increased, the rate of corrosion of the cathode gradually diminishes until (simultaneously with the commencing deposition of silver) it entirely ceases. In such a case, during the period that the amount of current passing is small, the whole of it traverses the cyanide of potassium, and no silver is deposited, but immediately that the amount becomes too large to be wholly conveyed by that salt, a portion traverses the salt of silver also, and deposition of that metal commences. By increasing still further the strength of the current, a large amount traverses the silver salt, and the rate of deposition of silver increases, but approximately the same amount of current appears to still traverse the free cyanide of potassium. The results in the present experiment show that if now the temperature be raised the same relative proportions of current pass through the silver salt and free cyanide of potassium as in the cold solution. They are, therefore, consistent with the inference that no corrosion, nor any difference of corrosion, of the cathode was produced by rise of temperature.

INFLUENCE OF STRENGTH OF CURRENT.

Experiment 19.—The influence of difference of strength of two currents of equal electromotive force was now tried. A current from three elements of zinc and platinum in dilute sulphuric acid was divided and passed through the coils of a differential galvanometer, and through two portions of a solution containing 100 grains of cyanide of potassium (of 86·65 per cent.) per ounce of water, and ·271 grain of silver dissolved in the solution of each glass, with anodes of sheet platinum and cathodes of sheet silver. Wire resistance was inserted in one of the circuits, and any variation of the currents indicated by the galvanometer. The currents were also passed through two argento-cyanide of potassium solutions in order to measure their amounts. After six hours' action at 54·5deg. Fahr.,

In the Circuit of the Greater Current

	Grain.		Grain.	
The silver cathode in the corroding solution had gained	·110	=	·0183	per hour.
The one in the depositing solution had gained	1·618	=	·2693	„
The silver anode in the depositing solution had lost	1·992	=	·332	„

In the Circuit of the Lesser Current

	Grain.		Grain.	
The silver cathode in the corroding solution had lost	·075	=	·0125	per hour.
The one in the depositing solution had gained	·160	=	·0266	„
The silver anode in the depositing solution had lost.....................	·572	=	·0953	„
The silver comparison plate in the corroding solution had lost	·599	=	·0998	„

Remarks.—The greatest current exercised the most protective power. Gas was evolved freely from the cathode with the stronger current, and less freely from that with the lesser current.

A large number of experiments were made expressly to test the question whether difference of electromotive force alone, independently of difference of strength of current, affected the rate of corrosion; but the difficulties of ensuring perfect uniformity in all the other conditions which affected the corrosion were so great that sufficiently decisive results were not obtained.

THE COST OF ELECTRIC LIGHTING AS COMPARED WITH GAS.*

Eight years ago the electric light was only used for scenic effects in theatres, or for dissolving views, but not for ordinary illumination. Since that time, the number of systems for producing the electric light has become so great that it is impossible to mention all. The present paper will, therefore, only deal with those systems that have come more prominently into notice, viz.:—In Belgium, the Serrin, Jaspar,

* Abstract of a paper read before the Liege Association of Engineers, by Mons. J. Dumont, railway engineer to the Belgian Government.

Digitized by Google

Siemens, Jablochkoff, Soleil, Edison, Maxim, Swan, and Brush systems; in France, the Serrin, Jablochkoff, Werdermann, Reynier, De Meritens, Lontin, Gérard, Jamin, Soleil, Gramme, and Brush; in Germany, the Siemens and Jablochkoff; in England, the Brush, Jablochkoff, Siemens, Brockie, Crompton, Soleil, Swan, and Lane-Fox; in the United States, the Brush, Weston, Jaël, Edison, and Maxim; in Russia, the Jablochkoff and Siemens; and, in Holland, the Jablochkoff, Jaspar, and Siemens. To obtain a general idea of the electric light from an economical point of view, I will first establish the cost, based upon the yield of light per horse power, irrespective of any particular system, and then the actual cost of various installations on different systems, calling the former "general prices," and the latter "actual prices."

General Prices.

In the following observations, the unit of luminosity will be taken as that produced by a Carcel lamp (9·6 standard candles) burning 42 grammes (nearly 1½oz. avoirdupois) of refined colza oil per hour; 7 centimes (nearly ¾d.) as the cost of a horse power produced by steam-engine; and, in comparison with gas, the burner consuming 140 litres (nearly 5 cubic feet) of gas per hour with the intensity of a Carcel flame. In practice, a horse-power is capable of producing 200 Carcel flames with large single-light electric arc lamps; 100 Carcels with medium single-light ditto; 50 Carcels with Jablochkoff "candles" and some forms of regulator; 25 Carcels with incandescent lamps *in pleno;* and 10 Carcels with some incandescent lamps *in vacuo*. The cost per hour in carbons for electric lamps may be put as follows:—

15c. (1½d.)	for large lamps of	500	Carcels.
18c. (1¾d.)	„ medium „	250	„
10c. (1d.)	„ small „	150	„
15c. (1½d.)	„ Jablochkoff candles of	50	„
6c. (½d.)	„ Werdermann lamps of	25	„

The cost of fittings amounts to 2,000f. (£80) for a large lamp, 1,800f. (£72) for a medium lamp, 1,000f. (£40) for a small lamp, 500f. (£20) for a lamp of from 25 to 50 Carcels, and 60f. (48s.) for an incandescent lamp *in vacuo*. By means of the above data, the cost price of illumination by the electric lamps of various intensities may be arrived at, with the supposition of the following durations of lighting:—600 hours yearly for installations where illumination is only required for certain periods of the year; 1,500 hours for house lighting; and 4,000 hours for cases in which the illumination extends over at least 10 hours a day:—

1.—*Cost of Lighting per Hour with Lamps of* 500 *Carcels.*

	Period of Illumination.		
	600 hrs.	1,500 hrs.	4,000 hrs.
	Cents.	Cents.	Cents.
Motor—3 horse-power, at 7c.	21·0	21·0	21·0
Carbons	15·0	15·0	15·0
Interest on capital and depreciation of installation (2,000f.=£80), at 12 per cent. per annum	40·0	13·3	6·0
Totals	76·0	49·3	42·0

2. *Cost of Lighting per Hour with Lamps of* 250 *Carcels.*

	Cents.	Cents.	Cents.
Motor—2½ horse-power, at 7c.	17·5	17·5	17·5
Carbons	18·0	18·0	18·0
Interest, &c., on 1,800f. (£72), at 12 per cent. per annum	35·0	14·4	5·4
Totals	70·5	49·9	40·9

3. *Do., with Lamps of* 150 *Carcels.*

	Cents.	Cents.	Cents.
Motor—1½ horse-power at 7c.	10·5	10·5	10·5
Carbons	10·0	10·0	10·0
Interest, &c., on 1,000f. (£40), at 12 per cent. per annum	20·0	8·0	3·0
Totals	40·5	28·5	23·5

4. *Do., with Lamps of* 50 *Carcels.*

	Cents.	Cents.	Cents.
Motor—1 horse-power, at 7c.	7·0	7·0	7·0
Carbons	15·0	15·0	15·0
Interest, &c., on 500f. (£20) at 12 per cent per annum	10·0	4·0	1·5
Totals	32·0	26·0	23·5

5. *Do., with Lamps of* 25 *Carcels.*

	Cents.	Cents.	Cents.
Motor—1 horse-power, at 7c.	7·0	7·0	7·0
Carbons	6·0	6·0	6·0
Interest, &c., on 500f. (£20), at 12 per cent. per annum	10·0	4·0	1·5
Totals	23·0	17·0	14·5

6. *Do., with Incandescent Lamps of* 1 *Carcel.*

	Cents.	Cents.	Cents.
Motor—0·1 horse-power, at 7c.	0·7	0·7	0·7
Carbons (if lamps cost 5f. = 4s., and last 1,000 hours)	0·5	0·5	0·5
Interest, &c., on 60f. (48s.), at 12 per cent. per annum	1·2	0·4	0·18
Totals	2·4	1·6	1·38

The prices thus established are for—(1) illumination from a great distance, with Serren, Siemens, or Brush regulators; (2) with Jasper or Siemens regulators; (4) with Jablochkoff candles; and (5) with Werdermann incandescent lamps.

On the other hand, the cost of laying down gas in works is, on an average, 30f. (24s.) per burner, consuming 140 litres (nearly 5 cubic feet) of gas per hour, and giving the light of 1 Carcel flame. Therefore, the light of a gas-burner costs per hour the following prices, according to the charge, whether 30c. (3d.) or 15c. (1½d.) per cubic metre (35·3 cubic feet); that is to say, 7s. or 3s. 6d. per 1,000 cubic feet:—

	Period of Illumination.		
	600 hrs.	1,500 hrs.	4,000 hrs.
	Cents.	Cents.	Cents.
Gas burned, 140 litres per hour, at 30c. per cubic metre	4·2	4·2	4·2
Interest and depreciation on 30f. (24s.), at 12 per cent. per annum	0·6	0·2	0·1
Totals	4·8	4·4	4·3
Gas burned, 140 litres per hour at 15c. per cubic metre	2·1	2·1	2·1
Interest and depreciation on 30f. (24s.), at 12 per cent. per annum	0·6	0·2	0·1
Totals	2·7	2·3	2·2

By means of these comparative cost prices for electric and gas lighting, the following table has been compiled, in which the prices are reduced to the Carcel flame (9·6 standard candles) taken as the unit of luminous intensity:—

	Cost per Carcel per Hour.		
	600 hrs.	1,500 hrs.	4,000 hrs.
	Cents.	Cents.	Cents.
1. Gas burner, yielding a flame equal to 1 Carcel, and consuming 140 litres per hour, at 30c. per cubic metre	4·80	4·40	4·29
2. Similar gas burner with gas at 15c. per cubic metre	2·70	2·30	2·20
3. Electric lamps of 500 Carcel units	0·15	0·10	0·08
4. Electric lamps of 250 Carcel units	0·28	0·19	0·16
5. Electric lamps of 150 Carcel units	0·27	0·19	0·16

Digitized by Google

	Cost per Carcel per Hour.		
	600 hrs.	1,500 hrs.	4,000 hrs.
	Cents.	Cents.	Cents.
6. Electric lamps of 50 Carcel units	0·64	0·52	0·47
7. Electric lamps of 25 Carcel units	0·92	0·98	0·58
8. Electric lamps of 1 Carcel unit (incandescent *in vacuo*)	2·40	1·60	1·38

If the electric light could be usefully distributed in the space to be illuminated, it would in all cases be more economical than gas; but practical experiments show that 20 ordinary gas burners can only be replaced by an electric lamp of 250 Carcels (2,400 candles), by two lamps of 50 Carcels (480 candles), or by four of 25 Carcels (240 candles). In this case, as in all cases where it is adopted, a total illuminating power is obtained which is greater than that yielded by the gas which it has replaced.

ACTUAL PRICES.

Illumination of the Telegraph Office at the Brussels Northern Terminus by the Jaspar System.—This is effected by three Jaspar regulators, which supersede 70 gas-burners, each consuming 140 litres per hour, each regulator having a luminous intensity of 235 Carcels (2,256 candles). The comparative cost of producing the light, calculated for a daily period of four hours, is, therefore, as follows:—

Electric Light.		
Motive power	2f. 84c.	
Carbons	0 56	
Interest and depreciation, at 10 per cent.	0 42	
Total for electric light (Jaspar) ...	3f. 82c.	(3s. 0½d.)
Gas.		
Consumption of 70 burners, at 15c. per cubic metre	1f. 45c.	
Breakage of glasses	0 15	
Interest and depreciation, at 10 per cent.	0 24	
Total for gas	1f. 84c.	(1s. 5½d.)

Whence it follows that the electric Carcel unit costs 0·0054f., and the gas ditto 0·0265f. Be it remarked, however, that the motive power is obtained from a gas-engine, which is dearer than steam.

Illumination of the Telegraph Office at the Brussels Northern Terminus by the Jablochkoff System.—In accordance with an estimate made in 1879, the illumination of the same room would require six Jablochkoff candles of 40 Carcels each, the cost per hour being—

Motive power	2f. 840c.
Carbons	0 900
Interest on capital and depreciation, at 10 per cent. per annum	0 387
Total (Jablochkoff)	4f. 127c.

or 0·017f. per Carcel per hour, compared with 0·0265f. for gas.

Illumination of the Place des Nations, Brussels, by the Jaspar System.—Admitting a daily mean of six hours, the cost is—

Electric Light.	
Motive power	2f. 69c.
Carbons	0 56
Interest and depreciation, at 10 per cent. per annum	0 29
Total (Jaspar)	3f. 54c.
Gas.	
Gas consumed	1f. 02c.
Interest and depreciation, at 10 per cent. per annum	0 19
Total (gas)	1f. 21c.

As the total intensity of the electric light is 705 Carcels, and that of gas about 40, the cost of the Jaspar Carcel is 0·00502f. per hour, and of the gas 0·03f.

(TO BE CONTINUED.)

PRACTICAL TELEPHONY.

(CONTINUED FROM PAGE 191.)

The words four batteries, &c., in the third line from bottom of page 189, July 7th, should read one battery, &c.

SEVEN POINT.—This switch, Fig. 40, is similar to the six point, except that it converts the trembling bell *c* into a single stroke when the switch is in the central position, so as to avoid the possible break of circuit when speaking through the contact breaker in bell *c*.

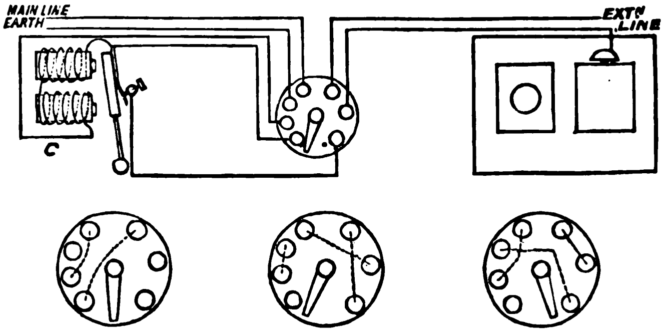

FIG. 40.

In all cases where three or more lines have to be provided with switches, the before mentioned switches would not answer the purpose. It has therefore been necessary to construct what are practically small exchanges, having indicators, &c., varying in number from three upwards. They are also fitted with a bell to call attention. One of these for four lines and the connections are shown in Fig. 41 on next page. The line from instrument consists of a flexible cord fitted with a jack (Fig. 42). This can be pushed under any of the springs under their respective annunciators, taking care that the insulated side is against the earth plate, on which the springs press in their normal position. Communication can then be carried on with that particular line, taking care to close the shutter when done; the jack can be removed or left until another call arrives, which if from another line will, of course, necessitate putting the jack under the spring corresponding to that number. If any two of the lines require to be put through, it is done by means of the double jack cord provided (*i.e.*, a cord with a jack attached to each end), taking the same precaution to put the insulated side against the earth plate and to close the shutters. When the communication is finished it should be indicated by one of the

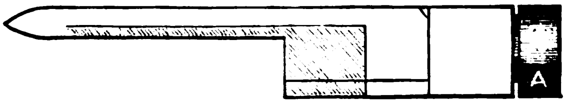

FIG. 42.

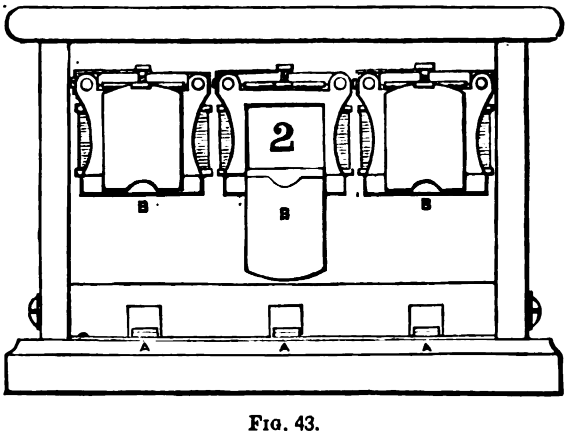

FIG. 43.

speakers pressing his button, which will cause both shutters to fall, which is the signal to disconnect. The cord and jacks must then be withdrawn. The bell is actuated by a single local cell which may, however, form part of the ordinary battery. It is obvious that with any increase in the number of lines it is only necessary to increase the number of the annunciators and springs. Figs. 43 and 44 show the front and back view of a

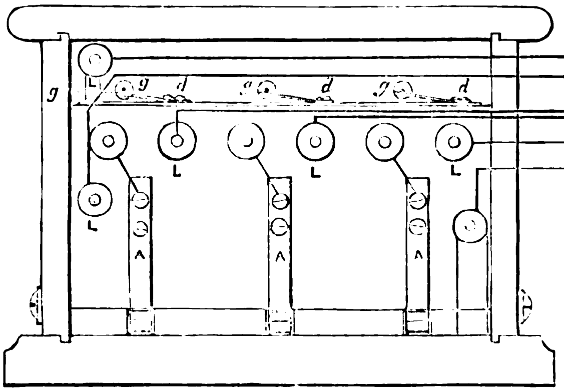

FIG. 44.

three-drop annunciator. A A A slipper springs, B B B annunciators, *g g g*, *d d d* local bell contact, L L L line terminals. The terminals at the left hand are for the local bell, and should be marked B B, and not L L.

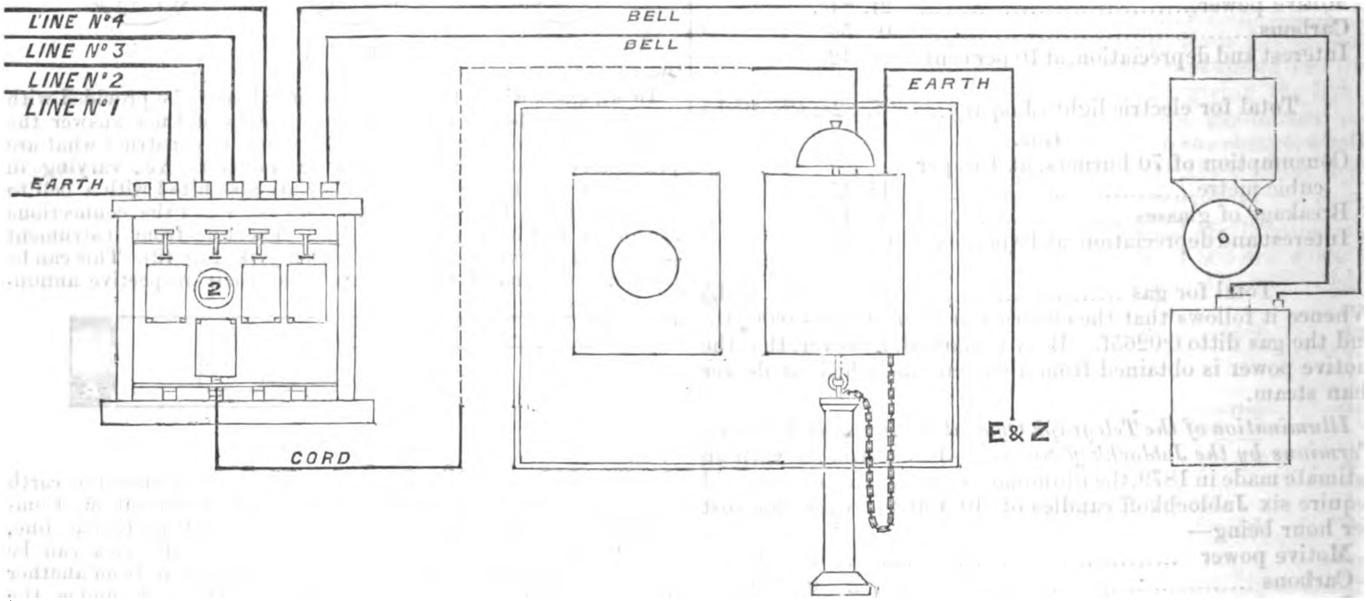

FIG. 41.

RELAYS.—Relays are not much required in telephony. There are instances, however, where they may be employed with advantage. The office of a relay is to close a local circuit (which may consist of a battery and bell, or any other apparatus) when actuated by a line current circulating through its coils. In adjusting single current relays the following points must be observed. The particular construction of the relay is unimportant. The contact screw must be so adjusted that when the armature is firmly on it there is room for a piece of paper to pass between the poles and the armature. The screw which limits the range or play of the armature must be so adjusted that the armature only fairly leaves the contact screw. The tension of the spring must be only sufficient to bring the armature into contact with the upper stop screw. The contact points between the armature and contact screw must be faced with platinum. Relays are used in the instruments, where three or more are in circuit, to avoid introducing the resistance of the bells into the circuit, and also to prevent them interfering with each other when ringing, from their making and breaking contact at different times. They are also necessary on long lines, where, from the resistance of the line, the arriving current has not strength enough to ring the bell, but quite sufficient to attract the armature and close the local bell circuit.

(TO BE CONTINUED.)

THE EASTERN TELEGRAPH COMPANY (LIMITED).

The twenty-second half-yearly ordinary general meeting of the Eastern Telegraph Company (Limited) was held on Thursday, July 12, 1883, at the City Terminus Hotel, Cannon-street, London, under the presidency of John Pender, Esq., M.P., chairman of the Company.

The notice convening the meeting and the minutes of the previous meeting having been read and confirmed, and the report having been taken as read,

The CHAIRMAN said: Before making my general remarks, I will draw your attention to the figures. The revenue for the six months ended March 31, 1883, amounted to £328,405 against, in the corresponding period of last year, £321,810, being an increase of £6,595. We had exceptionally large receipts for telegrams for Egypt, not only in the half year under review, but also in the previous six months. In order to earn this increased amount of money it was necessary to keep open the communication with Egypt at any cost. I may mention that we expended last year on this exceptional account over £62,000, employing in the service no fewer than six ships. Some of these expenses were charged against the September half year, but many items, though incurred before September, appear only in the present accounts. Everything has now been charged, and the result of the year's working must, we think, be considered satisfactory by the shareholders. The South African Company, of which the Eastern Company hold almost all the shares, paid us the same dividend as last year—namely, 8 per cent. They previously paid 10 per cent., but the reason of the fall from 10 to 8 per cent. has been the cessation of hostilities. Looking at the interests of the Cape, I shall be very sorry if the same causes which enabled us to earn 10 per cent. should again occur [hear, hear], because there is nothing so disastrous to a country as war. Though we may reap an immediate benefit of 1 or 2 per cent. from war, I think that a prosperous country and good trade are likely to be much more beneficial to us. Therefore I should much prefer that we grew from 8 per cent. owing to commercial prosperity, than to the breaking out of any hostilities. The ordinary expenses of the Company were in the half year £87,827, as compared with £75,140 in the corresponding period of last year, or an increase of £12,687. This increase is accounted for as follows:—Working expenses at stations, an increase of £8,863. Since March, 1882, we have opened six new stations—namely, Athens, Karystos, Trieste, Corfu, Port Said, and Tripoli, so that this half year's accounts bear their part of the expenses. In addition to the working expenses we have likewise charged a large proportion of the outfit of these stations for instruments, furniture, &c., against revenue, which might fairly have been charged to capital expenditure. Therefore this £12,000 increase is not of a permanent character, for we have taken a good proportion of it from revenue to establish these offices which might have been placed to capital. I am quite sure that the shareholders will approve that course, as it is not desirable to increase the capital account if we can possibly help it. General expenses in London show an increase of £1,016. This is mainly attributable to stationery, printing, and law charges. With respect to the former we have recently had printed and distributed a large number of tariff books containing numerous engraved maps on steel, showing the different telegraph systems of the principal countries of Europe, India, the far East, South Africa, and our colonies in working connection with Eastern Company's lines. With regard to these books that we have published, they will give a good idea of the extent of the ramifications of this telegraph system. If any one is desirous of possessing a copy we will give t him after the meeting is over, and if there are not sufficient here to supply a copy to all we shall be glad to forward them on receiving applications at the office. I think it will be instructive and will give the shareholders even greater confidence than they have at the present moment in the working of this great system.

The expenses of the foreign agencies show an increase of £594, arising from the additional stations and agencies opened. We have been obliged at Vienna to open an agency. The depreciation of cable stores shows an increase of £135, and maintenance ships' reserve fund an increase of £1,900. This is owing to an additional ship. The ship "Volta," which now comes into the books for depreciation, is the cause of the increase of the amount I have re-

Digitized by Google

ferred to in the ships' reserve fund. There is another expense—it is a small one—in regard to the protection of submarine cables. I refer to the conference which was held at Paris on the question. Then there is also another special item this half year which was agreed to at the last meeting, namely, the bonus to the staff, which was suggested and carried unanimously by the meeting, on account of the arduous work which they had to do owing to the Egyptian war. That amounted to about £1,000. Now, I think I have given you a pretty fair idea of our increases and decreases; but I am happy to say that, after all this additional expense, we have carried to reserve fund this year £85,000, as against £75,000, at the same period last year. There is another point which, I daresay, will give satisfaction to the shareholders. I have mentioned that whenever we could see our way to do so, consistently with the best interests of the company, we should be prepared to increase our dividend. The last dividend we paid was at the rate of 5½ per cent. We are now prepared to add by way of bonus an additional ½ per cent., which will make for the past year 6 per cent., and at the same time we carry this large increase of £10,000 to the reserve fund. I think, all things considered, we have shown that the past year has been one that has been largely beneficial to the company. At the last meeting I gave you a sketch, and a very full one, of what had occurred during the Egyptian war—the great sacrifices the Company made in the interest, I would say, of the world—and I suppose I may use that word. At all events, we made great sacrifices, certainly in the interest of the British Government and of those who were conducting the war in Egypt. I repeat now that I believe that that war would not have been as short-lived as it was had it not been for the extraordinary facilities which the Commander-in-Chief had through the telegraph, enabling him to keep up his communications with the Admiral and the other branches of the expedition in such a way as to continue the campaign as a compact whole. I believe the telegraph did signal service at the time, and I am glad to say in doing this service I believe it was appreciated to a certain extent. We have not lost by it, and I think the arrangements we were able to make so far justify the large expenditure of £62,000 which we made to give that service. It has given us a very important position not only with the British Government, but also with other Governments. At this very moment another nation—a friendly nation—is engaged in war in the far East. What do they do? They know the benefit we conferred on our own Government by the telegraphic communication we brought to bear in assisting them, and the French Government have therefore come to us, and I believe at the present moment there is a convention signed by that Government which will enable the Eastern Extension Company to carry the telegraph system from Saigon to Tonquin. This is what I should call an additional feeder to our own system, as everything done in that direction brings so much more traffic to the Eastern system.

Now, since I last had the pleasure of addressing you we have made another important addition to our system by laying down a new line—a triplicate line in the Red Sea from Suez to Aden. This had almost become a necessity. At the Cape we had opened up a system, its departing point being Aden. The Government of the Cape considered that they were entitled to a good service, as they were paying us a handsome subsidy. It has been our first consideration always, even before the question of dividend, to make our service so efficient that it would be impossible for any one to make complaints and say to us, "You are not doing this service to our satisfaction, and we must invite others to come forward." There has been some grumbling at the Cape at the rate charged. As you are aware, the Eastern Company are the largest shareholders in the South African system, but we have now shown—and I hope the Cape people will appreciate what we have done—that we desire to meet their wishes. By laying this third cable in the Red Sea it has enabled us to give them such a service as could not possibly be equalled by any other system. That has caused us considerable expense, but looking at the development generally of the East and the far East—a development, which, so far as China is concerned, is but beginning—I regard any expenditure in that direction as likely in the future, and in the very early futuie, to bring very good fruits indeed.

There is one other thing I am pleased to say to-day—that we have not a single ship employed at this moment, and, further, all our cables are in good working order. But it was only yesterday that we got the news of one repair, and the day before the news of another repair. As I have often stated to you, if we could only avoid these repairs we could make very handsome additions to our dividend. We must not crow too much, but still at the present moment we have all our ships in harbour, and the longer they remain there the better.

There is another incident I have to allude to. We are in favour of duplication—I may almost say of triplication. We made an arrangement with the Suez Canal Company for the construction of a land line from Port Said to Suez. We had that line opened, I think, on the 28th of June, and I believe it was only opened about twenty-four hours when our land line through Egypt, on which we were entirely dependent, was run into by a railway train, and the traffic was suspended for some days on that line. Fortunately, however, having secured the line along the Canal, there was no interruption to our traffic. That is a very important incident as showing the value of a duplicate system. The loss to us would have been very serious if the whole of our traffic to India and the far East had been interrupted; but the fact that this line along the Canal was completed just in the nick of time saved us a very serious loss. This question of the Suez Canal, as well as the success of it, has been, as you are all aware, very much before the public of late. I think we, the Eastern Telegraph Company, may claim to be a very important factor in the great success which has attended the Suez Canal. In olden times ships very often carried their own letters; at all events, letters were carried by steam. The ships had to wait sometimes one month, sometimes six weeks, and sometimes longer for cargoes; but now a ship sails, telegraphic communication is made to the point of destination of the ship, and arrangements are made for the cargo. The ship arrives there, is reloaded, and back she goes to England, and that is all done through submarine telegraphy. The submarine telegraph is almost the beginning of every operation that takes place in the East, and I may say almost the end of the operation. Consequently it is one of the most important factors in commercial life at the present moment.

Now, gentlemen, I think I have pretty well given you the different points of interest, and I need not detain you longer excepting with regard to the financial question. I think it will be in the recollection of many within this room that I mentioned we were going to issue debenture stock, the object being to take up and pay off the existing debenture stock, and replace it with debenture stock at a lower rate of interest. This we have resolved to do, and you have had before you a circular to that effect. I think it is not necessary for me to say much in favour of this stock. For a long time at these meetings I have said that submarine telegraphy was a very speculative system; that we placed the cable in the bottom of the sea, and therefore that it was difficult to realise what age that cable would live to. But our experience year after year has satisfied us that the submarine telegraph is about as good a property as a railway property. We know where a break occurs, and can pick the cable up; consequently, every year satisfies us that it is not an uncertain property. As to how long a cable may live, that is a question I cannot answer; but this I can say, that if you take up a cable, the core of it, the real heart, the part that transmits the thought, is as good as the day the cable was laid down, and we have now an experience in these cables of something like fifteen years.

Sir JAMES ANDERSON: Seventeen years.

The CHAIRMAN: Seventeen years; consequently, I have no hesitation now in recommending our debenture stock as a sound and good investment. The prospectus in which we invite the public to subscribe has only been published a very short time; and, looking at the other appeals for money, or rather the other invitations to subscribe capital, I do not see anything before the public at the present moment as good or as safe as this debenture stock of the Eastern Telegraph Company. We have got already applications for a considerable amount of the stock. It will pay about 4¼ per cent. By the money we shall thus receive we shall pay off our present debentures, and we shall pay for this new cable and other things connected with capital. I look for a considerable saving from this reconstruction of our debenture debt. With these remarks I beg to move:—"That the printed report and accounts of the directors to 31st March, 1883, submitted to this meeting, be and they are hereby received and adopted; that a dividend on the Preference shares of the Company to the 30th June, 1883, at the rate of 6 per cent. per annum be paid, less income tax; and that, in accordance with the directors' recommendation, a dividend be and is now declared of 2s. 6d. per share, with a bonus of 1s. per share, both free of income tax on the ordinary shares of the Company, making, with the previous payments by way of dividends on account, a total payment of 6 per cent. on those shares for the year ended 31st March, 1883."

The VICE-CHAIRMAN (the Marquis of Tweeddale): I beg to second that.

Mr. FISHER: Are not debenture stocks generally founded upon some tangible security? In a railway there is the rolling stock, besides the rails and other things that you can get at; but where is the security for a thing at the bottom of the sea?

Mr. HURST: I think the security is as valuable as any railway security, or any other stock. We have an extensive business, and the cables have been working exceedingly well for a long time past. We have been going on from year to year rather improving our prospects, and if there is no security for our debenture stock I am sure that there is no security for anything in existence. You talk of the 3 per cent. consols, there is no tangible security there [laughter], but at the same time it is so sound that property is regarded as secure if it is in the consols. In the same manner, the property of the Eastern Telegraph Company is certainly a security, and a very ample security for this debenture stock. Therefore I think the debentures will very soon be taken up, and people who wish to invest in a good security will be very apt and very happy to take it up. With regard to properties generally, if a man goes to invest money, generally speaking he has an immense difficulty in being quite certain that the security's sound, but here I think you have something far more solid than you would find in almost any other company in existence. We must thank the directors for the manner in which they have conducted this business. They have taken care always to supply the wants of the public. The consequence has been that year after year our property has been improving, and therefore I think there is no doubt about the security offered by this debenture stock; and, in fact, any man who wishes to lay out his money well, and safely, and soundly, cannot do better than take it up.

The CHAIRMAN: The answer I have to give is very short. I have stated to you what we believe the property to be; but when I tell you that we are earning £400,000 a year net, and that the interest on this debenture stock only takes £20,000 of it, you can easily see that it is a very good security. As to its permanency, we also show you from experience that it is as sound as any railway, as we can repair the cables, and we do so, and we always keep up the property in a thorough state of efficiency. I therefore think it is not necessary for me to say anything more about it, but I may add just look at the reserve fund. There we have £569,000 or £570,000, That is a very large sum. You may be perfectly satisfied that the security is a good one, notwithstanding it is lying at the bottom of the sea. [The chairman then put the resolution, and declared it to be carried unanimously.] That, gentlemen, concludes the business of the day.

Mr. JOHN NEWTON: I have much pleasure in rising to move a vote of thanks to the chairman of the Company. I think shareholders in telegraph companies are very greatly indebted to Mr. Pender for what he has done, not only in this Company but in all the others. It has fallen to my lot to criticise the doings of this body of directors, and I must say that what I have done in the past has been productive of some good. But the result has been more beneficial to the shareholders than we could have anticipated some time ago. The very fact that it is possible to place our mortgage debenture stock (for it must not be forgotten that it is mortgage debenture stock) at 4 per cent., or practically so, is evidence of the solid property we now possess. I should not think for a moment of comparing it with consols, as it does not yet bear that comparison; but that it is a very good investment there can be no question. I think it is very greatly due to the capacity, energy, and foresight of the directors that we are in such a position. At the same time the shareholders have not received the advantage which I think they should have received [hear, hear]. Six per cent. is nothing like what was held out on the original formation of the Company. But those who have bought the property at the low prices of some years ago have derived great advantage. I foresaw myself what a great advantage telegraph property would be. I knew it was not possible to conduct the operations of commerce between this country and the East without the use of the telegraph. I have had no doubt of this view for

Digitized by Google

twenty years past. That is why I have always taken a great interest in this class of property. I have very great pleasure in moving a vote of thanks to you and to your colleagues for the manner in which you have conducted our business for years past.

A SHAREHOLDER: I second the motion.

The CHAIRMAN: I am very much obliged to you for the way in which you have complimented the Board—my colleagues and myself—for our foresight and energy. It has really been a labour of deep interest this telegraph system. Every day it is expanding, and every day it requires increased attention, and that attention is now valuable from the fact that it is based upon considerable experience. I entirely sympathise with Mr. Newton in his remarks about the dividends, and I entirely sympathise in the expression of approval given to his remarks by the general body of the shareholders present. But just let me tell you the cause. If we had open messages, as we expected they would be when we put this system first before the public, we should have been paying about 60 per cent. to-day instead of 6 per cent.; but such has been the ingenuity of the merchants that this has been prevented. When I tell you that a man spends from £1,000 to £10,000 a year in telegrams, you will see how anxious he is to reduce that amount in every possible way in his power, and the public using the telegraph have shown great ingenuity, and beaten us. I believe in many instances two or three words give as much information as would fill a page of this paper. We cannot contend against them, and we are obliged to accept the position, and this coding system is one that will go on. Still, it is equally remarkable the hold the telegraph has had on the commercial public that we are able to keep up the dividend we are now paying, notwithstanding all this ingenuity. With the present system of telegraphs it would have been impossible to carry the messages had they been all in open language. We must therefore be satisfied with a moderate dividend. I hope, however, that it will grow. If not it will not be the fault of those who sit on this side of the table. I beg to thank you.

The proceedings then terminated.

WEST COAST OF AMERICA TELEGRAPH COMPANY.

The sixth ordinary general meeting of this Company was held on Thursday at the Cannon-street Hotel. Mr. Robinson Kendal in the chair.

Mr. F. S. ROBINSON (the secretary) read the notice convening the meeting, and the report of the directors was taken as read.

The CHAIRMAN said: I have now, gentlemen, to move the adoption of the report and accounts, which are in the hands of all the shareholders, and which you have taken as read. This report is of course not so satisfactory as we could wish, but under all the conditions, which are practically known to every one who either reads the newspapers or is interested in trade, it is perhaps almost as good, if not better than any one expected it to be. For a time we have laboured under serious disadvantages, owing to the continuance of the deplorable war, and the consequent utter stagnation of trade at Lima and other important places in Peru, and it is perhaps in some degree a matter for congratulation that the Company is in the comparatively favourable and progressive condition shown in the report. Up to the 31st December last year the earnings of the Company were £38,908 2s. 10d., against £32,356 15s. 11d. for the previous year, showing a net balance of profit, after paying debenture interest and all charges, of £7,667 11s. 1d., a result which, as the report says, though not altogether satisfactory, is yet far from unpromising. Since the date up to which the report is made out the company has made further progress, and now I am able to confirm what is said in the report—viz., that the mortgage and all other liabilities and arrears of the company, set down at a sum of £20,465 8s. 5d. in the balance sheet for 1881, have been discharged and extinguished. With the discharge of all these arrears and liabilities, incurred through a variety of conditions—the cutting of our cables, the continuance of the war, and the paralysation of trade—the company has assumed a much more favourable position, and the outlook in every sense may be fairly regarded as far from uncheering. Our receipts have continued to increase under all the adverse circumstances under which our operations have had to be carried on, and nothing is required but an assurance of peace and a revival of trade to still further augment our income, and enable us to render to the shareholders an account with which no one will have reason to be dissatisfied. Not that I have either seen or heard any expression of dissatisfaction in regard to the present report, but quite the reverse—everything, in fact, that I have seen or heard being in regard to our accounts, to our economies, and to our working, not only of a satisfactory, but of an agreeable and even complimentary character. In our next report we hope we shall not only show a considerable increase in our income, but a diminution in our expenditure, for the large item for interest will have disappeared—except in regard to a small amount now extinguished—and there will be also various other economies which will tend in a greater or lesser degree, if all things go well, and as we expect, to increase the net profit of the Company's working operations. What the future may bring to us it is not for me to anticipate, but besides the satisfaction of saying that all our past accumulations and indebtednesses are now paid off, I have also the satisfaction of saying that, looking inquiringly into matters, our progress and our prospects are the reverse of discouraging. Our steamer has been overhauled and put into a complete state of repair, as verified by the underwriters' survey and the certificate we have received, and I am pleased to say that through a variety of causes her value to us has been enhanced, so much so, indeed, that we have increased rather than decreased the amount of insurance for which she is covered. The claim of this Company upon the Chilian Government is still in abeyance, but I am not without hope that in a few weeks, or perhaps days, we may hear something of a more definite and satisfactory character. Since the report was issued to the shareholders we have received from our manager on the coast a letter in which he says he hopes either to write us by next mail, or to wire to us, a fresh offer on behalf of the Government for a settlement of a part of our claim, the remainder of the claim being submitted for adjudication to the International Commission now sitting and deciding upon claims arising out of the conflict between Chili and Peru. Whatever the result may be in regard to this claim, I need hardly assure the shareholders that the constant and persistent efforts of the Board have been exerted to bring about a settlement just and honourable alike to this Company and to the Chilian Government. At a time when armies were being decimated, and cities were being sacked, and trade and progress arrested and paralysed, it was, perhaps, too much to expect that the Chilian Government would seriously entertain and settle our claim, but now that matters have assumed a calmer aspect, and peace seems to be in some may assured, as every one hopes, we may reasonably appeal, after so long waiting, to the Chilian Government to do us justice, and in view of the traditions, the honourable traditions, of that Government, we hope we shall not appeal uselessly or in vain.

Mr. MACANDREW seconded the motion.

In reply to a shareholder,

The CHAIRMAN stated that they claimed a very large sum from the Chilian Government, but he would rather not enter into particulars.

The motion was then put and carried unanimously.

The CHAIRMAN said that in view of the encouraging prospects of the Company, and not only the possibility but the probability of their being in a position to form an adequate reserve, and of being able to declare a dividend, he had to move "That the directors of this Company be and are hereby empowered to declare interim dividends out of such profits as may from time to time be available."

Mr. CAMPBELL seconded the motion, which was carried.

Mr. T. F. Campbell and Mr. W. E. MacAndrew, the retiring directors, were re-elected, and Mr. J. Weise (of Turquand, Youngs, and Co.), the retiring auditor, was reappointed.—The proceedings then terminated.

THE DIRECT UNITED STATES CABLE COMPANY.

Report of the directors for the six months ending 30th June, 1883, to be presented at the twelfth ordinary general meeting of the Company, to be held at the Cannon-street Hotel, Cannon-street, on Thursday, the 26th inst., 1883:—With this report the directors submit the usual statements of account for the half year ending June 30, 1883, which, with the half year's accounts to 31st December last, presented at the ordinary general meeting on the 9th February last, show the financial result of the sixth year's working of the Company. The revenue for the half year, after deducting out-payments, amounted to £70,529 19s. 5d. The working and other expenses for the same period, including interest on debentures and income-tax, amounted to £19,315 8s. 9d., leaving a balance of £51,214 10s. 8d. as the net profit of the half year, making, with £1,286 16s. brought forward from the previous half year, a total of £52,501 6s. 8d. Three quarterly interim dividends of 1¼ per cent. each, amounting to £45,532 10s., have been declared and paid at the usual times during the financial year, and a final dividend of 5s. per share is now proposed, making, with the three interim dividends, 5 per cent for the year, being a total distribution of £60,710. The appropriation of the above balance of £52,501 6s. 8d. on the revenue account is thus shown:—Interim dividend for quarter ending 31st March, 1883, £15,177 10s.; final dividend now proposed, £15,177 10s.; carried to reserve fund, thereby increasing it to £315,000, £19,877 17s. 3d.; depreciation of spare cable tank at Halifax, £416 1s. 6d.; carried forward to next account, £1,812 7s. 11d. — £52,501 6s. 8d. The depression in the commercial markets and general slackness of business has had an effect upon Atlantic telegraph cable traffic, the earnings from which show a slight decrease during the past six months compared with the corresponding period in 1881, when the tariff was the same. The establishment of the independent office in New York has given general satisfaction. Pursuant to the provisions of the Articles of Association, two of the directors, viz.:—John Pender, Esq., M.P., and E. M. Underdown, Esq., retire by rotation, and being eligible, offer themselves for re-election. Mr. John G. Griffiths and Mr. John Sawyer, the auditors, retire pursuant to the Articles of Association, and offer themselves for re-election.

NOTES.

SIAM.—Telegraphic communication has now been established with Siam.

ELECTRICAL WORK IN ENGLAND.—Fighting before a Parliamentary Committee.

EARTHQUAKE.—A violent shock of earthquake was felt at Catanzaro, in Calabria, yesterday morning.

KILLED BY LIGHTNING.—On Saturday last at Gobb's Oak, near Cheshunt, a man was killed by lightning while taking shelter under a tree.

VENEZUELA.—The land lines in Venezuela, which have been interrupted more or less during the past five months, are now again in working order.

LOUISVILLE.—The Edison Company is to light the exhibition here. It is stated that 15 dynamos will be used to supply light to 4,500 16 candle-power lamps.

EXETER.—A committee of the Town Council has been formed to report on the best means to be adopted for lighting by electricity the new lunatic asylum.

NEWINGTON.—A stormy vestry meeting was held last week to consider the electric lighting scheme and the Board of Trade inquiry. The meeting, after some disturbance, was adjourned.

SS. "SCOTIA."—The Telegraph Construction and Maintenance Company's steamer "Scotia" had paid out up to noon, 23rd inst., 205 knots of telegraph cable from Vladivostock towards Nagasaki.

YORK.—It is said that the exhibition at York, held during the Royal Agricultural Show week, owes much of its success to the electric light. This work was carried out by Messrs. Crompton and Co.

LUMINOSITY.—Hittorf, in recent experiments, using iridium for platinum and 2,400 elements, found that though the iridium anode was melted, the gas media, whether of nitrogen, hydrogen, or oxygen, remained perfectly dark.

ELECTRIC LIGHT IN HOTELS.—As part of the improvements introduced on their new service to the continent by the Great Eastern Railway Company, the Parkestone station refreshment rooms and hotel are lighted by electricity.

TELEPHONE CONSOLIDATION IN AMERICA.—All the New England exchanges, including those owned by Lowell and the Boston Exchange, are to be consolidated into one company under the title of the New England Telephone Company.

THE VIENNA EXHIBITION.—Owing to the slowness with which exhibits are arriving at Vienna, the exhibition, the opening of which was fixed for 1st August, has been postponed, no date for its commencement being yet decided upon.

ELECTRIC LIGHT AT THE HOUSE OF COMMONS.—The experimental lighting of the dining room and library of the House of Commons by electricity has, it is said, been so successful that the system is to be adopted for a permanency.

THE COMMITTEE ON THE PROVISIONAL ORDERS.—The evidence taken before this committee is lengthy and interesting, but we are compelled to leave the consideration of it for another issue, preferring to deal with it as a whole rather than in parts.

MAXIM-WESTON COMPANY AND THE CITY LIGHTING.—Mr. H. Watt, managing director of this company, writes to *The Times* that "after mature consideration" the Board have decided to discontinue their City lighting, because it is unprofitable. How, under the circumstances, could it be otherwise?

SOCIETY OF ARTS CONVERSAZIONE.—The *conversazione* held on Wednesday evening at the Fisheries Exhibition, was in every respect a great success. There was a large attendance, and the gardens, as well as the annexes of the exhibition, were lit by thousands of electric lamps and Chinese lanterns.

A HIGH RETURN.—Mr. Weston is said to treat gun cotton to form the filament for an incandescent lamp, and thus to get a carbon wire 75 ohms resistance, and expects with an E.M.F. of 52·5 volts, and a current of ·7 ampere, to get a theoretic efficiency of 20·3 lamps per horse-power, and a practical efficiency of 11 lamps per horse-power.

"THE ELECTRICAL REVIEW" (American).—This paper is appropriating Mr. Sprague's work on secondary batteries, as given in the *English Mechanic*, but so far without giving any credit to the paper in which the articles originally appeared. Our American friend may see a difference, which we fail to see, between stealing literary matter and stealing one's coat.

EASTERN EXTENSION TELEGRAPH COMPANY.—We understand that this company is about concluding an agreement with the French Government with a view to the laying of two new cables in the Eastern seas. These cables will connect Tonquin and Saigon, also Hong Kong and Saigon. The former is to be completed within four months of the present time.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—The twelfth meeting of this association will be held at Rouen, from the 16th to 25th August. Besides the papers to be read, a number of excursions are being arranged to Elbeuf, Dieppe, Havre, and Cherbourg, but the programme is not yet definitely settled. The town of Rouen itself possesses many attractions.

"GORDON'S PHYSICAL TREATISE ON ELECTRICITY."—We understand that the new edition of this work will be ready next month. The work has been revised throughout and considerably enlarged by the addition of new matter and illustrations. Full accounts will be found in it of the experiments of Bjerkness, Stroh, and Tribe. The publishers are Messrs. Sampson Low and Co.

TELEPHONY AND MORALITY.—A curious case has recently come before the American Courts. A telephone company stopped communication with a subscriber because the language used mainly consisted of expletives, and was unfitted to reach the ears of many who might accidentally overhear it, such as the young women employed in the exchanges. The company was upheld by the Court.

OVERHEAD WIRES IN TOWNS. — At the meeting of the Liverpool Workhouse Committee on 19th inst. the increasing multiplicity of telephone wires overhead was discussed upon a recommendation to allow the Liverpool Telephone Company permission to fix a support for a wire upon the top of the workhouse. Several members expressed anticipations of danger from the network now covering the city. The application in question was postponed for a fortnight.

LIVERPOOL.—The Liverpool Electric Supply Company have fitted up Eberle's restaurant in Dale-street with Woodhouse and Rawson's incandescent lamps. The dynamo is

Digitized by Google

driven by a gas engine, and steadiness of light is secured, and risk of breakdown obviated by the use of storage batteries. As this establishment requires artificial light all day, the advantages of electric light over gas are most marked. The installation has been effected under the superintendence of Messrs. Holmes and Vaudrey.

House Lighting by Batteries.—As we suspected, the daily papers are quite wrong about the pretty exhibit of the Leeds Forge Company at the recent Metal Trades Exhibition. The large marine boiler, fitted up as a drawing room, was lighted not by "storage batteries," but by primary batteries, the company supplying them being the Economic Electric Company, of Rathbone-place and Soho-square. The battery employed was an improved form of Daniell, with modified solutions. The installation, thanks to the portable nature of the generator, was put up in a few hours, and ran successfully to the end.

Atlantic Cables.—Most of our exchanges, and many of the English correspondents in America, amuse themselves from time to time in spreading canards about more Atlantic cables. A note in our last issue, under the heading "Sheepish," has brought more than one reply showing the ignorance of the ordinary reporter; and as we then said we could without much difficulty lay our hands upon the paper originating the error, so we could without difficulty show how these statements about Atlantic cables arise. Generally there is no foundation for the rumours, except words purposely said to keep unsettled, and to allow of manipulation on, the Stock Exchange.

The Postmaster-General's Report.—The twenty-ninth annual report of the Postmaster-General just issued shows that there has been an increase of 746,156 in the number of telegrams during the past year as compared with an increase of nearly two millions in the year 1881-2. This diminution in the rate of increase is partly accounted for by the occurrence of two Easters in the financial year. The total number of telegrams amounted to 32,092,026. The sum of £37,000 has been spent on improved telegraphic communication with Ireland, and £13,000 for the new cable depôt at Woolwich. It is contemplated fitting up a cable ship at a cost of £46,000 the department at present having no cable ship of its own.

Eccentric Electricity Underground.—During a heavy storm a week ago, while the guides were showing a large party through the Luray caverns in Virginia, the lightning struck one of the electric light wires and was carried into the caves, while it ran over the wires from one end to the other. The electric light globes were shivered into fragments, and the lightning gathered into big balls along the wire and exploded with loud reports. The scene for several minutes was terrific beyond description. The lightning flashing along wires looked like fiery serpents. One bolt shot from the wires and scattered the stalactites of the bridal chamber. When it disappeared, some of the party were left in total darkness.—*Electrical World.*

The Electric Light in Newington.—An inquiry was opened on Saturday last before Major Marindin, R.E., on behalf of the Board of Trade, at the Vestry Hall, Walworth-road, with respect to the application of the Newington Vestry for a license to supply the electric light, which was opposed by certain ratepayers.—Mr. Littler, Q.C., who represented the parish authorities, said the vestry had applied for a license for the whole parish, but sought only to make it compulsory over a small portion, and that at present it would only propose to spend £20,000, which would not increase the rates more than about one penny in the pound.—Mr. L. J. Dunham (vestry clerk) was examined, and said that the resolution to apply for a license was carried by 26 to 11.

Cheap Telegrams.—In the House of Commons, on the 19th inst., Mr. R. Paget asked the Postmaster-General if he would be good enough to consider the advisability of establishing a cheaper rate for telegrams sent from the country to London (or any other populous place having two or more postal deliveries during the day), subject to the condition that such telegrams should not be specially delivered, but should be sent to their address by the earliest available postal delivery of letters.—Mr. Fawcett replied that careful consideration had been given to the proposal contained in the question of the hon. member, but it was not thought desirable to depart from the principle, which in his opinion was a very important one, of maintaining uniformity of charge.

Forged Telegrams.—It is stated that on Monday morning a large number of forged telegrams, purporting to be sent by Dublin stockbrokers, were forwarded to brokers in London ordering the purchase and sale of large quantities of stock. Fortunately some circumstances occurred in London to arouse suspicion, and the consequence was the telegrams were not acted upon. An inquiry has been instituted, but as the messages were hand printed it will be probably difficult to trace their authors. By the Post Office (Protection) Bill, now before the House of Commons, Mr. Fawcett will propose to render liable to twelve months' hard labour any person "who forges a telegram, or utters a telegram knowing the same to be forged, whether he had or had not an intent to defraud."

International Electrical Exhibition, Vienna, 1883.—As far as time and space will allow, a fountain is to be erected in the centre of the Rotunda similar to the fountains in front of the St. Peter's at Rome. By a pump, driven by electricity and requiring 40 horse-power, a considerable quantity of water will be conveyed to a height of from seven to eight metres, falling into an intercepting vessel below, and from there into the basin, which will likewise have its water columns play during the exhibition to a height of 25 metres. The Société Gramme, from Paris, who exhibited for the first time at the Universal Exhibition in the year 1873 the electric transmission of force by driving a small pump, and employed about 2 horse-power, will carry out the installation above mentioned, and exhibit the engines then employed as historical models.

The Edison Light in Italy.—On the 28th of June the Comitato per le Applicazioni Dell' Elettricità Sistema Edison in Italia inaugurated the central station for electric lighting in Milan with a *soirée* in the Teatro Manzoni. The central station of Milan, erected near the cathedral, has now four Edison 1,200-lamp dynamos, and has room for eight more dynamos of the same size. The construction began in November, 1882, and the plant was ready to start in June, 1883. The company made contracts for supplying light to 3,500 lamps, especially for cafés, restaurants, clubs, and some stores in the most frequented part of the city. In the district which is supplied with Mr. Edison's underground system, there are two theatres, one of which is the celebrated Theatre Della Scala, which will be completely lighted for the end of this year with about 2,000 lamps. The station is now working regularly with about 500 lamps, to be increased daily as the wiring of the lamps is completed.

The Electric Lighting Act.—A parliamentary paper has been issued containing the report of the Board of Trade respecting the applications to and proceedings of the Board under the Electric Lighting Act of 1882. From this state-

Digitized by Google

ment it appears that by the 21st of December last, the date prescribed by the rules which the Board of Trade has issued. 106 applications had been received. Twenty-three of these were promoted by local authorities, and eighty-three by companies; ninety-seven of the applications related to places in England and Wales, eight to places in Scotland, and one to Belfast, Ireland; thirty-five related to London and the suburbs. A list of the applications is given in an appendix. A fee of £50 was received with each application, and in ten cases where separate orders have been granted for various districts included in one application an additional fee of £10 has been charged by the Board of Trade. The total amount of fees received amounts to £5,400. The time for lodging objections was limited by the rules to two months from the date of the first advertisement of the application. It was, however, extended by a new rule to the 1st of February. Eventually, after a consideration of the orders as deposited, and of the objections which had been lodged against them, the Board of Trade determined upon the principles upon which the applications should be dealt with, and on the 28th of February they circulated model clauses for adoption with such modifications as might appear to be necessary. The charges to the public are more than covered by the fees received. The report is supplemented by several appendices.

Electric Lighting of the Strand.—Sir Frederick Bramwell, C.E., gave evidence on this question on Tuesday before the Select Committee of the House of Commons on Electric Lighting. He said he had given a great deal of attention to electric lighting, was a shareholder in the Edison Company, and had seen the system of that company at work in New York. In his opinion the Edison Company could supply electricity in the Strand district as cheaply as any other company. They would have to lay down mains, and might find themselves working for one or two years at a loss. Gas was likely to become cheaper every day, and would be the strongest possible competitor. No doubt, Sir Frederick Bramwell said in cross-examination, at first, light for light, electricity would be dearer than gas. It would be equal to a price of 7s. 6d. per 1,000 feet of gas. A man might be willing to pay 50 or 100 per cent. more for a light he preferred than for gas. At any rate, for a long time the prices would be widely different. Sir John Lubbock, chairman of the Edison Company, stated that Mr. Edison was to have half profits after 5 per cent. was paid to the shareholders. Mr. Edison would receive £20,000 by anticipation, to be repaid out of profits. Evidence was also given by Dr. Hopkinson, electrician of the Edison Company, and other witnesses. The question immediately before the committee was the confirmation of the provisonal orders obtained by the Edison and Swan companies for the electric lighting of the Strand district. These two companies are working in harmony, but are opposed by the Strand District Board of Works, and partially by the Jablochkoff Company, who seek admission into the district.

A New Enemy of the Telephone.—A delegation of telephone subscribers from the Eighteenth Ward called at the office of Superintendent M'Kinstry yesterday afternoon, says the Cleveland *Herald*, and complained that some new wire that had been strung along through that ward was interfering with the workings of their telephones, at times rendering them perfectly useless. The wire was discovered to be that of the Postal Telegraph Company. On Harvard-street, east of Broadway, and on the Bedford-road, the postal line runs within eight or ten feet of the telephone line for a distance of three or four poles, and although an ordinary wire at the distance would produce no effect whatever, the system of telegraph in use by the Postal Company renders the telephone line almost of no value. The sound produced by the enormous induction from one heavy copper wire of the Postal system is much like that of a fish-horn. While the Leggo system of telegraph, which has already been described in these columns, was used over the new company's wire, some trouble was anticipated in the working of the telephone, but it was not thought a material difficulty. Afterward, however, the Gray harmonic system, which the *Herald* has also described, was put in use on the line, and the induction was so great that much complaint began coming in. At first the owners could not imagine what was the difficulty, and even electricians did not believe it possible that wires so far distant could produce the effect. It appears, however, that the system now in use over the line is particularly conducive to heavy induction, and the wires will be raised still farther away from the telephone line. Mr. M'Kinstry appeared before the Board of Improvements last night and asked for permission to have the wire changed, which was granted him.—*Electrical World.*

An Electric Railway.—The Electric Railway at Wimbledon, which it was expected would have carried passengers during the recent Rifle Association Meeting, made a start on Friday week; and a train, with Earl Brownlow, Sir Henry Halford, and eighteen other members of the association, ran the length of the line, about a mile, at a speed (six miles an hour) which earned for the engineer the congratulations of the party. The experiment has been, unfortunately, a rough one, and the conditions under which it has been carried out are very detrimental to the reputation which the system is susceptible of attaining. The familiar track of light rails laid down twenty-two years ago, with carriages of the same date, the sleepers loose in the sandy soil, is not the kind of line for an electricity-driven train to be shown off upon, especially when the wheels of the cars are so much furrowed that their bearing surfaces bump on every chair of the rails they pass over. The system of propulsion is by current generated from a Weston dynamo, worked by a 12 horse-power Robey engine, and conveyed and returned by two flat copper bands about an inch broad, each laid at the bottom of a groove in long wood bearers stretched midway between the lines of rails, and supported on square wood blocks saturated with pitch. The insulation appears to be perfect. The motor consists of four external magnets coupled together in similar poles, and an armature formed of sixteen magnets travelling in the interval between the external magnets and cutting all the lines of force. It is mounted on one of the ordinary carriages, and the current is drawn off from and returned to the conductors by two trailing chains dropping within the conductor channels. The system has been put under trial by the Electric Motor Syndicate, the motor being the invention of Mr. Brown. The line is not being worked to the full extent of the power furnished, the engine only making 40 revolutions and the dynamo 300, whilst the normal rate of the latter should be 900 revolutions.

Lighting of the Steamer "Pilgrim."—The *Sanitary Engineer* of New York, in an article on the plumbing and lighting of this new steamer, of the Fall River Line, between Boston and New York—a steamer supposed to be the largest inland steamboat in the world—says of the lighting that it "is entirely by electricity. This work was done by the Edison Company for Isolated Lighting. The plant consists of one 'L' and two 'K' Edison dynamos, run by a special engine of about 100 horse-power, and some 940 incandescent lamps; of these about 550 are of 10 candle-power, and
